CHAPTER I
INTRODUCTION

On September 24, 1998, the U.S. Environmental Protection Agency (EPA) Administrator signed the final oxides of nitrogen (NO_x) State Implementation Plan (SIP) Call, a rule that called for NO_x emission reductions from point sources in 22 Eastern States and the District of Columbia (DC) (the SIP Call region). Among the type of sources potentially covered by this rule are stationary reciprocating internal combustion engines (RICE), which are a large contributor of NO_x emissions in the SIP Call region. On May 24, 1999, the DC Circuit Court of Appeals issued a stay on further implementation of the NO_x SIP Call, and agreed to hear motions from various parties opposed to implementation of the NO_x SIP Call. On March 3, 2000, a three-judge panel upheld most of the SIP Call provisions. This panel ruled, however, that EPA did not provide adequate notice of the final control level for RICE sources that EPA deemed highly cost effective. In response to this ruling, the EPA will re-propose the part of the NO_x SIP Call particular to RICE sources in the affected States in order to provide adequate notice to the public.

The data and results provided in this report update a previous report of the same name and dated June 7, 2000. The updates include incorporating RICE from Virginia and West Virginia, and modifying the fuel penalty estimate for lean-burn engines.

The analysis included in this report contains control cost estimates associated with the provisions of the re-proposal. This analysis shows that NO_x emission reductions for the large, affected RICEs under the NO_x SIP Call are expected to cost $532 per ton, on average. NO_x emissions within the control region are expected to be reduced by about 53,000 tons per 5 month ozone season in 2007 from what they would otherwise be without this program. Expected total annual costs for RICE NO_x controls under the NO_x SIP Call are $28 million.

This report provides information about the universe of potentially affected stationary RICEs, control cost modeling methods, scenario analyses, and caveats and uncertainties associated with this analysis. Chapter II describes the universe of potentially affected RICEs. Control cost modeling methods are described in Chapter III. Analysis results for the baseline analysis and sensitivity analyses are presented in Chapter IV. Chapter V describes some of the important caveats and uncertainties in this analysis.

All cost results presented in Chapter IV of this report are expressed in 1990 dollars. Where control cost equations listed in this report are expressed in year dollars other than 1990, that is noted in the applicable table. A 7 percent discount rate was used to express capital costs as annual equivalents. The choice of the 7 percent discount rate is based on guidance from the Office of Management and Budget (OMB).

CHAPTER II
UNIVERSE OF UNITS

Stationary RICEs generate electric power, pump gas or other fluids, or compress air for machinery. The primary non-utility application of internal combustion (IC) engines is in the natural gas industry to power compressors used for pipeline transportation, field gathering (collecting gas from wells), underground storage tanks, and in-gas processing plants. RICEs are separated into three design classes: 2 cycle (stroke) lean burn, 4-stroke lean burn, and 4-stroke rich burn. Each of these have design differences that affect both baseline emissions as well as the potential for emissions control.

Table II-1 presents information about the projected 2007 large RICE population in the NO_x SIP Call control region. The list of IC engines and NO_x estimates used in this analysis were supplied to The Pechan-Avanti Group (Pechan-Avanti) by EPA in two spreadsheets named lrge2-00b.123 on May 19, 2000, and ice3-2vawv.xls on August 2, 2000. These lists include the large RICEs in the entire States of Illinois, Indiana, Kentucky, Maryland, Massachusetts, New York, North Carolina, Ohio, Pennsylvania, South Carolina, Tennessee, Alabama, Georgia, Michigan, Missouri, Virginia, and West Virginia. It should be noted that 4 of the 201 engines included in the analysis are in the coarse grid. For this analysis, a large RICE was defined as having emissions greater than or equal to 1 ton per day (tpd) in 1995 (the base year of the analysis).

Table II-1 lists the number of large RICEs (units) in each State, and their respective NO_x emissions expressed in daily and 5-month ozone season terms. The average large RICE emits about 2 tpd, and this value does not vary much from State-to-State. Alabama is the only State in the control region with more than 10,000 tons of NO_x from large RICEs in the 5-month ozone season. Thirteen States have ozone season NO_x emissions from RICE engines in the range between 1,000 and 10,000 tons. States in the control region with no affected engines are Connecticut, New Jersey, Rhode Island, DC, and Wisconsin. Combined, these RICEs are estimated to contribute to more than 60,000 tons of NO_x emissions during the 2007 5-month ozone season.

There are 67 establishments (facilities or plants) with large affected RICEs in the control region, as noted in Table II-1. No State has more than 9 establishments.

Table II-1
Summary of 2007 Major RICE Engine Emissions by State

FIPs State	State	# of Establishments	# of RICE	Ozone Season NO_x (tons/5 months)	Ozone Season Daily NO_x (tpd)
01	Alabama	4	32	11,977	78.3
13	Georgia	2	11	4,561	29.8
17	Illinois	9	28	6,647	43.4
18	Indiana	6	17	5,199	34.0
21	Kentucky	6	10	3,083	20.1
24	Maryland	2	3	609	4.0
25	Massachusetts	1	4	933	6.1
26	Michigan	3	6	1,601	10.5
29	Missouri	4	5	1,401	9.2

54	West Virginia	4	7	1,101	7.2
	Total	**67**	**201**	**60,206**	**393.5**

CHAPTER III
CONTROL COST MODELING METHODS

NO_x controls applied to RICEs in this analysis were low-emission combustion (LEC) applied to lean burn gas-fired engines, non-selective catalytic reduction (NSCR) applied to rich burn gas-fired engines, and selective catalytic reduction (SCR) applied to oil-fired engines. The baseline control assumptions for each technology are 87 percent NO_x reduction for LEC, 90 percent for NSCR, and 90 percent for SCR.

Each control cost reference document reports control costs in specific year dollars. The EPA Alternative Control Techniques (ACT) document for RICEs reports costs in 1993 dollars. The capital cost estimates for LEC that were used in this analysis for controlling NO_x from lean burn gas-fired engines are reported in 1999 dollars. All costs were converted to 1990 dollars using National Income and Product Accounts gross domestic product implicit price deflator index from the Source of Current Business (DOC, 1999), as shown in Table III-1. Each EPA ACT document contains information about interest rates and the expected lifetime of each control technique. In estimating control costs for this analysis, the lifetime from the ACT document was used, and a 7 percent discount rate. The estimated equipment lifetime for IC engine controls is 15 years.

In the September 1998 analysis (Pechan-Avanti, 1998), it was assumed that all gas-fired engines were lean burn (because the Source Classification Codes [SCCs] did not distinguish lean and rich burn). This analysis assumes two thirds of gas-fired engines are lean burn, while one third are rich burn. This provides a more accurate assessment of expected control costs for RICEs than in the September 1998 NO_x SIP Call cost report (Pechan-Avanti, 1998), where all gas-fired engines were assumed to be lean-burn. As more States submit point source data using SCCs that distinguish lean from rich-burn engines, more sophisticated analyses can be performed.

Control costs are estimated in this analysis using an ozone season cost per ton. For controls that operate year round, like LEC, the ozone season cost per ton is the total annualized cost (with 100 percent of both capital and operating cost) divided by the ozone season (5 month) tons reduced. For SCR and NSCR, only five months of the operating cost is counted in computing the total annualized cost.

The estimates of 1995 and 2007 NO_x emissions for the (large) IC engines affected by the NO_x SIP Call were received in an EPA data base. Most of the units in this data base had a zero for NO_x control efficiency. None of the non-zero NO_x control efficiencies were more than 15 percent. Therefore, it was determined that any of the existing controls in place would not affect the performance of the control options needed to meet the NO_x SIP Call requirements. Therefore, when SCR, at an 80 percent control level, was applied to an oil-fired IC engine, and that engine had a 10 percent efficient control in 1995, the NO_x emissions and emission reductions were computed as:

Table III-1
Implicit Price Deflators

Year	Gross Domestic Product	Conversion to 1990 Dollars
1990	92.00	1.000
1991	96.27	0.955
1992	99.13	0.928
1993	101.84	0.903
1994	104.13	0.884
1995	106.75	0.862
1996	108.91	0.845
1997	111.00	0.829
1998	112.32	0.819
1999	113.52	0.810

SOURCE: DOC, 1999.

$$2007\ \mathit{Uncontrolled}\ NO_x\ '\ [2007\ NO_x\ \mathit{emissions}]\ (\ \frac{1}{(1\ \&\ 0.1)}$$

Then, 2007 post-control NO_x was estimated as:

$$2007\ \mathit{Post\&Control}\ NO_x\ '\ [2007\ \mathit{Uncontrolled}\ NO_x]\ (\ (1\ \&\ \mathit{control\ efficiency})$$

This method changes the State-level NO_x emission estimates slightly, in States with existing controls, but allows consistent application of different control efficiencies in the sensitivity analyses.

This cost analysis uses revised estimates of the costs of installing and operating LEC NO_x controls on lean-burn natural gas-fired RICEs. Table III-2 summarizes the revised control cost information for this control technique. Note that all of the costs in this table are presented in 1993 dollars (as were the NO_x ACT document costs). Capital costs were converted from 1999 dollars to 1993 dollars using the gross domestic product implicit price deflators. The maintenance labor rate was converted to 1993 dollars using the Bureau of Labor Statistics (BLS) Employment Cost Index Historical Listing (BLS, 2000). The BLS indices are shown in Table III-3.

The LEC capital cost estimates for 2,000, 4,000, and 8,000 horsepower (hp) engines were provided by Cooper Energy (Hibbard, 1999a; 1999b) and used directly in this analysis. Maintenance and overhead costs were estimated using recommended methods from the EPA Office of Air Quality Planning and Standards (OAQPS) Control Cost Manual (Vatavuk, 1999). The maintenance cost is the maintenance labor rate times the number of expected additional maintenance hours per year (500). The overhead cost is 60 percent of the maintenance labor value. The fuel penalty is based on an estimated one percent decrease in natural gas use. Taxes, insurance, and administrative costs are estimated to be 4 percent of the capital cost. The compliance test cost is $2,440, which is the same value that was estimated in the EPA ACT document (EPA, 1993).

Table III-4 summarizes the ozone season NO_x cost effectiveness values for each of the three engine type control option combinations that were evaluated in this analysis. More detailed information on the control cost equation development for this analysis is presented in Appendix A.

Table III-2
Low-Emission Combustion Cost Components for Lean-Burn RICEs

Size (hp)	Annual Hours	Capital Cost*	Maintenance Cost	Overhead Cost	Fuel Penalty	Taxes, Insurance Admin.	Compliance Test	O&M Cost
2,000	8,000	$337,493	$13,113	$7,868	$-1,643	$13,500	$2,440	$35,277
4,000	8,000	$552,620	$13,113	$7,868	$-2,987	$22,105	$2,440	$42,539
8,000	8,000	$594,784	$13,113	$7,868	$-5,867	$23,791	$2,440	$41,345

NOTE: *Costs are expressed in 1993 dollars.

Unit Costs for RICE Analysis

Engine Type	Fuel	Control Option	Percentage Reduction	Ozone Season Cost Effectiveness ($/ton)
IC Engine-Lean Burn	Natural Gas	Low Emission Combustion	87%	422
IC Engine-Rich Burn	Natural Gas	Non-selective Catalytic Reduction	90%	342
IC Engine-All	Oil	Selective Catalytic Reduction	90%	1,066

CHAPTER IV
RESULTS

This chapter describes the analysis of the cost impacts for RICEs. This analysis estimates control costs and NO_x emission reductions for large RICEs affected under the NO_x SIP Call re-proposal.

Table IV-1 summarizes the analysis results at the domain level for the main analysis and six sensitivity control scenarios examined. Table IV-2 describes the key assumptions in the baseline analysis as well as how each of the alternative control scenarios (i.e., sensitivity analyses) differs from the baseline. Table IV-3 provides all of the same information as Table IV-1, but with more information reported. Table IV-3 reports results for each of the three engine types, and shows all of the before and after control NO_x emission values (annual tons, 5 month ozone season tons, and ozone season daily tons). The remaining tables in Chapter IV, Tables IV-4 through IV-10, provide State-level results for each scenario.

The average cost per ton (ozone season) for the main analysis is $532 per ton. This ozone season cost per ton is affected mostly by the gas-fired engine control costs. Oil-fired engines are about 3 percent of the population of large RICEs. While oil-fired engine costs are just above $1,000 per ton, they have a negligible influence on regionwide costs. Of the five oil-fired RICEs, four are in Massachusetts and one is in Missouri. Massachusetts has the highest control costs per ton because all of its affected RICEs are oil-fired.

In Scenario B, the control efficiency for LEC applied to lean burn gas-fired engines is reduced to 82 percent. This increases the average cost per ton by about $20 per ton. (The total annual cost changes slightly from the main analysis. *This change is an artifact of the way the total annual cost is estimated, though. Expected annual costs would be the same in Scenarios B and C as they are in the main analysis.*) The RICE NO_x reduction drops by almost 2,000 ozone season tons in Scenario B.

Scenario C increases the NO_x control efficiency for lean burn engines to 90 percent. This additional emission reduction reduces the average cost per ton to about $520 per ton, which is about $12 per ton less than in the main analysis.

Scenario D changes the uncontrolled NO_x emission level for lean burn gas-fired engines to 13.7 grams per brake horsepower-hour (g/bhp-hr) from 16.8 g/bhp-hr. With fewer NO_x tons being reduced, this raises the cost per ton to about $603 per ton.

A control level of 1.2 g/bhp-hr in Scenario E produces the lowest average cost per ton of $513 (and the largest emission reduction).

Scenario F reduces annual operating hours to 6,500. This changes both the emission reductions and the costs. Compared with other scenarios, there are lower emission reductions and costs, and with a cost per ton $49 higher than that in the main analysis.

Scenario G retains the capital cost estimates that were used in the September 1998 Non-Electricity Generating Unit (EGU) cost analysis for the NO_x SIP Call. The capital costs used for this analysis were taken from the ACT document. The scenario has the same emission reductions as the main analysis, but with $334 per ton higher estimated costs.

Table IV-1
Reciprocating IC Engine Cost Analysis Summary

Scenario		Ozone Season NO_x Emissions 5 Month Tons	Ozone Season NO_x 5 Month Ton Reduction	Annual Cost ($1000)	Average Cost Per Ton	Percentage Reduction
A	Main Analysis	60,206	53,006	$28,222	$532	87.8%
B	Control Efficiency = 82%		51,002	$28,007	$549	84.5%
C	Control Efficiency = 91%		54,539	$28,387	$520	90.4%
D	Uncontrolled NO_x = 13.7 g/bhp-hr		52,181	$31,464	$603	84.9%
E	Control Level = 1.2 g/bhp-hr		55,305	$28,390	$513	92.4%
F	Annual Hours = 6,500	49,154	43,281	$25,134	$581	71.7%
G	Previous Capital Cost Values		53,006	$45,899	$866	87.8%

Costs are expressed in 1990 dollars.

Table IV-2
Main Analysis and Scenario Description

Source Category	Description
Main Analysis Scenario A	For lean-burn gas-fired engines, the uncontrolled NO_x emission level is 16.8 g/bhp-hr, the controlled NO_x level (with LEC) is 2.0 g/bhp-hr, the annual hours of operation are 8,000, and LEC costs are estimated as described in Chapter III.
Scenario B	Control level of 3g/bhp-hr for gas-fired lean burn engines
Scenario C	Control level of 1.5g/bhp-hr for gas-fired lean burn engines
Scenario D	Uncontrolled level of 13.7g/bhp-hr for gas-fired lean burn engines
Scenario E	Control level of 1.2g/bhp-hr for gas-fired lean burn engines
Scenario F	Annual operating hours reduced to 6,500 hours/year for gas-fired lean burn engines
Scenario G	Uses the same LEC costs applied to lean burn engines that were used in the September 1998 NO_x SIP call analysis

CHAPTER V
CAVEATS AND UNCERTAINTIES

Caveats and uncertainties associated with this cost analysis include:

1. Current knowledge about NO_x control techniques and costs is applied in this study. Advances such as alternative catalyst formulations may occur between now and when sources comply with this rulemaking that may lower costs. Scale economies can also lower per unit production costs as the market for these NO_x control techniques expands.

2. The alternative control techniques and corresponding emission reductions and costs may not apply to every unit within the source category. Many factors influence the performance and cost of any control technique. Because control technology references typically evaluate average retrofit situations, costs may be underestimated for the fraction of the source population with difficult to retrofit conditions. Difficult to retrofit conditions may be less of an issue for RICEs than for other point sources, however.

3. Control costs for large RICEs are estimated using cost estimates for 2,000, 4,000 and 8,000 hp engines. Cost estimates will be most uncertain where controls are being applied to large engines that are outside the 2,000 to 8,000 hp range.

4. Because States focused their efforts on reporting ozone season daily emissions, those are expected to be the most reliable emission estimates. The five-month ozone season values are sometimes reported by the States, and sometimes estimated by EPA using temporal allocation factors.

5. NO_x control efficiency estimates associated with source category-control strategy combinations are represented as point estimates. In practice, control effectiveness will vary by unit. The sensitivity analyses shown earlier in this report provide an indication of how cost effectiveness is affected by uncertainties in control efficiency.

6. Operating costs for LEC are probably overstated in this analysis because a slight fuel penalty for operating with LEC was applied. It is likely that fuel efficiency will increase with LEC.

7. Estimates of the fraction of the IC engine population that are lean burn versus rich burn are uncertain because the emission data bases used in this analysis do not usually make this distinction.

APPENDIX A
DETAILED CONTROL COST WORKSHEETS

APPENDIX A
DETAILED CONTROL COST WORKSHEETS

The details of the control cost and efficiency input parameters used in this analysis are provided in Tables A-1 through A-7 as shown below.

Table A-1	Scenario A - Main Analysis Unit Cost Calculations
Table A-2	Scenario B - Control Efficiency = 82%
Table A-3	Scenario C - Control Efficiency = 91%
Table A-4	Scenario D - Uncontrolled NO_x = 13.7 g/bhp-hr
Table A-5	Scenario E - Control Level = 1.2 g/bhp-hr
Table A-6	Scenario F - Annual Hours = 6,500
Table A-7	Scenario G - Previous Capital Cost Values

APPENDIX B
SOURCE CLASSIFICATION CODES AFFECTED BY THE NO_x SIP CALL

Table B-1
Source Classification Codes Affected by the NO_x SIP Call

20200202	Internal Combustion Engines; Industrial; Natural Gas; Reciprocating
20200204	Internal Combustion Engines; Industrial; Natural Gas; Reciprocating; Cogeneration
20200252	Internal Combustion Engines; Industrial; Natural Gas; 2-cycle Lean Burn
20200254	Internal Combustion Engines; Industrial; Natural Gas; 4-cycle Lean Burn
20200401	Internal Combustion Engines; Industrial; Large Bore Engine; Diesel
20200501	Internal Combustion Engines; Industrial; Residual/Crude Oil; Reciprocating
20300201	Internal Combustion Engines; Commercial/Institutional; Natural Gas; Reciprocating
