Notes:

1. Qualifiers: U = the compound/element was not detected above this value. J = value is estimated due to limitations found in the data validation. UJ = the compound/element was not detected above this value and the value is estimated due to limitations identified in the data validation. R = data was rejected due to major problems identified in the data validation. NJ = The value is estimated to indicate presumptive evidence of a compound/element.

Notes:

1. Qualifiers: U = the compound/element was not detected above this value. J = value is estimated due to limitations found in the data validation. UJ = the compound/element was not detected above this value and the value is estimated due to limitations identified in the data validation. R = data was rejected due to major problems identified in the data validation. NJ = The value is estimated to indicate presumptive evidence of a compound/element.

Notes:

1. Qualifiers: U = the compound/element was not detected above this value. J = value is estimated due to limitations found in the data validation. UJ = the compound/element was not detected above this value and the value is estimated due to limitations identified in the data validation. R = data was rejected due to major problems identified in the data validation. NJ = The value is estimated to indicate presumptive evidence of a compound/element.

Notes:

1. Qualifiers: U = the compound/element was not detected above this value. J = value is estimated due to limitations found in the data validation. UJ = the compound/element was not detected above this value and the value is estimated due to limitations identified in the data validation. R = data was rejected due to major problems identified in the data validation. NJ = The value is estimated to indicate presumptive evidence of a compound/element.

Notes:

1. Qualifiers: U = the compound/element was not detected above this value. J = value is estimated due to limitations found in the data validation. UJ = the compound/element was not detected above this value and the value is estimated due to limitations identified in the data validation. R = data was rejected due to major problems identified in the data validation. NJ = The value is estimated to indicate presumptive evidence of a compound/element.

Notes:

1. Qualifiers: U = the compound/element was not detected above this value. J = value is estimated due to limitations found in the data validation. UJ = the compound/element was not detected above this value and the value is estimated due to limitations identified in the data validation. R = data was rejected due to major problems identified in the data validation. NJ = The value is estimated to indicate presumptive evidence of a compound/element.

Notes:

1. Qualifiers: U = the compound/element was not detected above this value. J = value is estimated due to limitations found in the data validation. UJ = the compound/element was not detected above this value and the value is estimated due to limitations identified in the data validation. R = data was rejected due to major problems identified in the data validation. NJ = The value is estimated to indicate presumptive evidence of a compound/element.

Notes:

1. Qualifiers: U = the compound/element was not detected above this value. J = value is estimated due to limitations found in the data validation. UJ = the compound/element was not detected above this value and the value is estimated due to limitations identified in the data validation. R = data was rejected due to major problems identified in the data validation. NJ = The value is estimated to indicate presumptive evidence of a compound/element.

Appendix D
Environmental Chemistry of Lead, Antimony and Tungsten

Appendix D
Environmental Chemistry of Lead, Antimony and Tungsten

This appendix briefly summarizes components of the environmental chemistries of lead, antimony and tungsten of potential relevance to the Small Arms Ranges.

D.1 Lead

A significant body of literature exists on the environmental chemistry of lead (Pb), including a detailed evaluation of lead at the MMR Small Arms Ranges (discussed in Section 3.2.5 and below) by Clausen et al. (2007). The following is a brief summary of some of the principal aspects of the environmental chemistry of lead.

Lead is primarily present in the +2 oxidation state in the environment including surface soils, sediments and associated mineral phases. In natural surface waters, across the primary natural range of Eh and pH conditions, lead is primarily found as the hydrated Pb^{+2} cation where it bonds directly to other inorganic or organic species. A relatively small amount of lead in the environment is associated with organic compounds, primarily as tetravalent lead, much of which was historically associated with fuels including gasoline. Lead (+2) in the solid phase and as dissolved Pb^{+2} in water is relatively immobile in the environment. Lead can form a variety of stable mineral phases including lead phosphate related minerals (discussed in Section 4.1.1.2).

In soil-water systems, dissolved lead (as Pb^{+2}) may form a variety of adsorption complexes on soil particle surfaces, including quartz, organic humic material and iron, aluminum, and manganese oxides. Lead is often significantly more strongly adsorbed to mineral surfaces than other related divalent metals including copper (Cu^{+2}), cadmium (Cd^{+2}) and zinc (Zn^{+2}). This behavior is attributed lead's larger hydrolysis constant (log K = -7.71). Clausen et al. (2007) note that due to its ability to form covalent bonds with oxygen atoms on mineral surfaces and humic matter, lead is capable of significantly adsorbing to soil particles even under mildly acidic conditions (pH>4). This strong tendency of lead to sorb to soil/mineral surfaces is reflected in the relatively high range of equilibrium constant K_d values (27-185 ml/g) that have been estimated for soils at the Small Arms Ranges.

Some recent research (Sauvé et al. 2000a,b) has suggested that in the dissolved phase, lead may frequently not be present as the Pb^{+2} cation but rather may be bound to dissolved organic carbon (DOC), if present. Complexation to DOC may tend to increase the solubility of lead over levels predicted based upon theoretical mineral solubility products. However, as noted by Clausen et al. (2007), although dissolved organic carbon data is not available for pore-water at the Small Arms Ranges, DOC concentrations are believed to be low. This conclusion was based upon measured total organic carbon levels (TOC) in pore waters at certain ranges.

As discussed in Section 5.1.2, SPLP results indicate that leaching of lead is possible from certain Small Arms Range surface soils (such as was observed for G Range soil). This behavior is consistent with recent TCLP evaluations of firing lines reported in the literature (Dermatas et al. 2006), indicating lead leaching from firing line soils (possibly through lead carbonate precipitation dissolution). However, as emphasized by Clausen et al. (2007), lead leaching from surface soils under TCLP conditions does not correlate to significant lead migration in subsurface soils. In studies at selected Small Arms Ranges, these authors noted that essentially no lead was detected in lysimeter pore water beneath multiple ranges despite surface soil lead

concentrations in excess of 1,000 mg/Kg at certain locations. These results are also consistent with the fact that there have been very few detections of lead in groundwater at monitoring wells beneath the Small Arms Ranges.

Bricka et al. (1998) quantitatively modeled the potential for lead migration from surface soils to groundwater at MMR Small Arms Ranges, estimating a potential migration time of 150-300 years. Clausen et al. (2007) noted that a number of the technical assumptions used by Bricka were relatively conservative. It was also noted that some more recent modeling efforts have suggested migration times may be significantly longer than those estimated by Bricka et al.

D.2 Antimony

The environmental chemistry of antimony (Sb) has been somewhat less studied than that of lead. However, available literature information suggests that antimony might be somewhat more mobile in certain soil-water environments than lead, particularly under oxic conditions.

In a detailed review of the environmental chemistry of antimony, Krupta and Serne (2002) noted that under natural environmental conditions, antimony exists in the +5 and +3 oxidation states. In natural aqueous systems, Sb^{+5} and Sb^{+3} are considered to be the stable oxidation states under both oxidizing and reducing conditions, based upon equilibrium thermodynamic considerations. However, contrary to thermodynamic predictions, Sb+5 and Sb+3 have been found to co-exist under some aqueous environmental conditions. Thermodynamic Eh-pH calculations suggest that under oxic conditions and low to moderate chloride, sulfate, nitrate, and carbonate concentrations (<100 mg/L), the dominant dissolved antimony species may be the hydrolytic species $Sb(OH)_6^-$ and/or a series of oxyanion species.

Only limited information is available on the sorption behavior of antimony in soil-water systems. Some research (Crecelius et al. 1975) has indicated that in relatively clean Puget Sound sediments the majority of the total antimony present was bound to amorphous/extractable iron and aluminum compounds. If dissolved antimony (as Sb^{+5}) is present in a soil-water system as an anionic species (such as $Sb(OH)_6^-$ or an oxyanion) then it may be somewhat mobile. Under these conditions, adsorption to oxide and hydroxide mineral surfaces is predicted to become negligible as pH increases from neutral to more basic levels. Under more acidic pH conditions, the adsorption of Sb^{+5} to mineral surfaces is predicted to be more significant.

Relatively little quantitative partition coefficient research data is available for antimony. Results from a series of equilibrium batch experiments (Legoux et al. 1992) for sandy clay soil samples containing a significant quartz fraction, indicated K_d values (mL/g) ranging from ~2 to 122. [The dissolved antimony concentration was 1.6×10^{-8} M]. The strongest adsorption (highest K_d value) was observed under the most acidic conditions (pH -~5.9) while the weakest adsorption was observed under mildly alkaline conditions (pH - ~8.0). These quantitative results are consistent with the predicted adsorption behavior noted above.

Overall, available geochemical literature information suggests that antimony may be somewhat mobile in surface soils at certain Small Arms Ranges depending upon the range surface and subsurface soil mineralogy and geochemical conditions. This literature based prediction appears to be consistent with the detection of antimony in certain lysimeter samples, such as those from G Range and B Range. Literature information also suggests that the extent of any antimony mobility and possible migration into the vadose zone may be closely related to the

total antimony concentration in surface soil and the localized aqueous pH conditions. The potential for antimony migration into the vadose zone may be highest at locations where soil pH levels are slightly alkaline. Conversely, slightly acidic conditions would likely favor significant antimony adsorption to soil particles inhibiting subsurface migration.

D.3 Tungsten

Tungsten (W) is a Group VI transition metal with the highest boiling point (except carbon) and lowest vapor pressure of any element. Tungsten may exist in a variety of oxidation states (-2 to +6) and coordination numbers (5-9) making its chemical behavior among the more complex of the transition elements. Due to its rather unique properties, it is frequently alloyed with carbon or other metals and has been used in various munitions related components including bullets used at the Small Arms Ranges. Historically, tungsten had been considered to have somewhat limited chemical activity. However, recent studies suggest that the environmental chemistry of tungsten may be relatively complex.

In natural terrestrial systems, tungsten exists primarily in the form of oxo-rich tungstate minerals either as scheelite ($CaWO_4$) or wolframite ([Fe/Mn]WO_4). Surface rocks have been reported to typically contain tungsten in the range of 1.0-1.3 mg/Kg and natural surface soils at levels ranging from approximately 0.7 -2.7 mg/Kg. However, available terrestrial data is limited and localized areas may diverge significantly from these ranges.

As discussed in the detailed review by Koutsopyros et al. (2006), limited available information suggests that metallic tungsten will, in fact, slowly dissolve in water. Studies (Lassner and Schubert 1999) suggest that tungsten dissolution rates in distilled water, although generally slow at lower temperatures (38C) can over sufficient time periods generate measurable equilibrium tungsten aqueous phase concentrations. In more recent work on metallic tungsten, short term dissolution into distilled water has been reported to result in equilibrium aqueous phase concentrations of approximately 500 µg/L within three days (Braida et al. 2002). Dissolution rates on the order of 500 µg per day were reported over approximately one week time frames. In natural systems dissolution rates would be expected to vary markedly depending upon the chemistry of the natural water aqueous phase including the presence of complexing ligands. The solid phase form of tungsten (metallic or alloy), solid phase-water mixing ratios and overall hydrologic exposure factors are also expected to influence dissolution rates.

Under alkaline to neutral pH conditions, monomeric tungstate (WO_4^{2-}) is believed to the primary soluble phase. It is considered to be primarily stable above pH 6.2 in aqueous systems in the absence of complexing agents. However, in the presence of inorganic anions (including F and Cl) and/or naturally occurring organic matter, the formation of multiple soluble complexes is possible. Conversely, under even mildly acidic conditions, recent information (Koutsopyros et al. 2006) suggests that the monomeric tungstate may tend to polymerize to form multiple forms of isopolytungstates (including $W_7O_{24}^{-6}$) of potentially complex chemical structure.

Soluble aqueous phase tungsten species have been shown to undergo sorption reactions with various types of soils, as has been observed for a number of transition metals. Tungsten adsorption to naturally occurring clays (montmorillanite, illite, sigma sand and peat) has been observed (Dermatas et al. 2004). In these laboratory studies the most extensive adsorption of

aqueous phase tungsten (initially dissolved from munitions alloys) was found to occur to organic containing peat, suggesting W/organic humic-matter interactions may be environmentally important. For inorganic clays and sand, tungsten adsorption from the aqueous phase was also observed, albeit at lower levels. For inorganic mineral phases the primary mechanism for sorption was postulated to be chemisorption of the tungstate anion on reactive metal hydroxyl sites on the solid phase.

In these sorption studies, adsorbed tungsten was found to desorb from soils although the desorption isotherms were noted to be hysteretic, suggesting partial irreversibility. The extent of tungsten adsorption to clays and soils was observed to be potentially impacted by the presence of other anions in the aqueous phase. Soluble phosphate was observed to inhibit the adsorption of tungsten by organic containing peat soil, essentially enhancing the mobility of the tungsten. In other recent studies (Bednar et al. 2008), tungstate partition coefficients for soils were found to increase somewhat over time suggesting gradually increased soil sorption and potentially decreased mobility. Overall, these laboratory studies suggested that in environmental systems soluble aqueous phase tungsten can adsorb to soils and sediments with the strength of adsorption and extent of subsequent desorption dependent upon multiple soil chemistry factors.

Clausen et al. (2007, 2010) conducted detailed laboratory and field studies on the fate and transport of tungsten from ammunition fragments at small arms ranges at the Massachusetts Military Reservation (MMR). Results of these studies suggested that under certain conditions tungsten could be solubilized from residual metal fragments from small arms ammunition in surface soils and migrate into the relatively sandy subsurface soils. Surface soil tungsten concentrations ranging from 100 mg/Kg to in excess of 1,000 mg/Kg were observed in some small arms range berm areas (Clausen and Korte 2009). Background tungsten concentrations were reported to be less than 2 mg/Kg. Soil pore water results from shallow subsurface lysimeters indicated soluble aqueous tungsten concentrations ranging up to in excess of 300 mg/L at some locations. In one localized area groundwater monitoring data indicated that tungsten had, in fact, reached the relatively deep groundwater table (greater than 50 feet). Groundwater concentrations were generally found to be less than 25 µg/L although a significantly elevated (spike) concentration of approximately 560 µg/L was reported in one sample. Recent pore water tungsten concentrations at the Small Arms Ranges have generally been less than 1 mg/L. Recent groundwater concentrations have been less than 20 µg/L.

Results of associated laboratory soil tungsten migration studies (Clausen et al. 2010) suggested that rates of tungsten migration were likely impacted by a competition between soil sorption processes and variations in rainfall patterns and localized hydrogeologic conditions over time. Preliminary results of laboratory column studies suggested that although both tungstate and polytungstate species were found in near surface pore water, tungstate was the primary species found in groundwater.

Appendix E
Information for MassDEP

Appendix E
Information for MassDEP

As discussed in the main body of the report, none of the soil analytes detected at the Small Arms Ranges was determined to be a threat to groundwater. However, 10 analytes (i.e., 2,4-DNT, perchlorate, antimony, arsenic, cadmium, chromium, lead, nickel, dieldrin, and benzo(a)pyrene) were detected in soil at one or more Small Arms Ranges at concentrations exceeding MCP Method 1 S-1/GW-1 Standards (see Table 7-2 of the main Investigation Report). Nitroglycerin was detected at six active operational ranges at concentrations exceeding the calculated MCP Method 2 S-1 Standard. In addition, tungsten was detected at certain ranges at concentrations exceeding its Interim Risk-Based Soil Concentration (MassDEP 2012) and heptachloronaphthalene was detected at Succonsette Pond in one sample at a concentration that exceeded its Relative Experimental Potency (REP)-adjusted MCP Method 1 S-1/GW-1 Standard equivalent. A summary of these exceedances, including the Small Arms Range name, the analyte exhibiting the exceedance of its criterion, a descriptor for the averaging area, the analyte's frequency of detection, the number of exceedances of its criterion, its maximum detected concentration, and its average concentration within that averaging area, is provided in Table E.1. The MCP Method 1 S-1/GW-1 Standard (or its specifically noted alternative) and the MCP Method 2 S-1 Standard (for direct contact exposure only) also are shown in Table E.1.

The summary statistics provided in Table E.1 were calculated using data from all investigations conducted at the respective Small Arms Ranges. Various sampling methodologies were used during these investigations, including discrete samples; 5-point and 9-point composites samples; and multiple increment samples. Separate averages were computed for the identified averaging areas within each Small Arms Range using the combined discrete and composite sampling results and using the available multiple increment sampling results. Only those samples that were collected from within 3 feet of the ground surface (i.e., MCP "accessible" soil) were included in the averages.

The average concentration for each analyte provided in Table E.1 is range-specific and was calculated using all sample results (including the reported non-detections). Each Small Arms Range exhibiting an exceedance of its MCP Method 1 S-1/GW-1 Standard (or its specifically noted constituent-specific alternative comparison criterion) was subdivided into contiguous areas of approximately 10,000 square feet (or less) for the averaging. In general, the multiple increment sample footprints that were previously defined within these Small Arms Ranges were approximately 10,000 square feet or less, with the notable exceptions of the downrange multiple increment samples collected at SE Range, SW Range, and T Range. If multiple increment samples were collected from contiguous smaller areas, these smaller sampling areas were combined with adjacent parcels to create an averaging area of approximately 10,000 square feet. If an analyte was not detected in a sample being used to calculate an average, it was conservatively assumed that the analyte was present in that sample at ½ the sample-specific reporting limit. 2,4-DNT and nitroglycerin were detected in Range soils using both the SVOC (Methods 8270 and 8270C) and explosives (Method 8330 and 8330b) analytical methods. All of these methods are considered to be valid and each result was counted as a unique sample for this assessment. Results for the SVOC and explosives methods were tabulated separately.

At those locations where maintenance or response actions involving soil excavation and removal have been performed since 1999, (e.g., most of J Range and portions of K Range, T Range, Former B Range, Former D Range, and Former M-2 Range), only post-removal soil sampling results were utilized in the calculation of the averages to ensure that the contaminated soil that has already been removed from a range does not bias the assessment of the current conditions for that range. For those locations where tungsten-contaminated soil was removed as part of the 2006 Berm Maintenance Project (i.e., at B Range, C Range, G Range, I Range, J Range, K Range, and T Range), the results for the pre-remedial action (pre-removal) samples were not utilized if that portion of the berm has been scraped and removed.

At locations where replicate multiple increment samples were collected (i.e., B Range, Former B Range, C Range, Former C Range, D Range, Former D Range, E Range, G Range, GA and GB Ranges, H Range, I Range, J Range, K Range, KD Range (East), Former M-2 Range, N Range, O Range, SE Range, SW Range, T Range, and Succonsette Pond), each of the replicate results was used in the calculation of the average concentration.

As seen in Table E.1, in general, area average concentrations do not exceed the MCP Method 1 S-1/GW-1 or the Method 2 S-1 Standards (i.e., there are few bolded and yellow highlighted listed average concentrations). But at several (13) ranges there are average lead concentrations in a particular averaging area that exceed the Method 1 S-1/GW-1 Standard for lead. There were also three ranges with areas where the area-average concentration of dieldrin exceeded its Method 1 S-1/GW-1 Standard. There also were a few exceedances of 2,4-DNT, nitroglycerin, antimony, cadmium, and chromium. These exceedances are discussed below by specific range, averaging area, and sample type.

- B Range - The 2013 multiple increment samples for lead in Areas multiple increment 1, 2 and 3, (corresponding to the footprints of BR01A, BR02A and BR03A, see Figure 5-4B) and the sample for Rectangle 789 exceeded 300 mg/Kg.

- Former B Range - There were two areas where the average concentration of dieldrin exceeded its MCP Method 1 S-1/GW-1 Standard. These two areas correspond to the locations of samples SS73G, SS73J, and SS73K (Area 73FGIK) and samples SS73O and SS73M (Area 73OM1A) (see Figure 5-5A). Also at Former B Range, the average concentration of lead in discrete/composite samples from area 140KLMN exceeded the MCP Method 1 S-1/GW-1 Standard. Area 140KLMN includes sample locations SS140K through SS140N (see Figure 5-5A). The exceedances were observed in 2002 at location SS140L (2,410 mg/Kg at 0 to 0.5 feet bgs and 477 at 1.5 to 2.0 feet bgs). Three multiple increment post-excavation confirmatory samples collected in 2008 (SSARFBBB3 and SSSARFBTL10) and 2009 (TTSARFB1) from nearby excavation areas were below the MCP Method 1 S-1/GW-1 Standard.

- C Range - The 2013 multiple increment samples for lead in Areas multiple increment 1 and multiple increment 2 (corresponding to the footprints of CR01A and CR02A, see Figure 5-6B) exceeded 300 mg/Kg. There were no previous samples collected from these areas.

- D Range - The 2013 multiple increment sample for lead from Area 1 (corresponding to the footprint of DR01A) exceeded the MCP Method 1 S-1/GW-1 Standard. There were no previous samples collected from this area.

- Former D Range - The average concentration of lead in the combined discrete/composite samples from Area 135GSTUWY exceeded the MCP Method 1 S-1/GW-1 Standard. This area lies between two previously excavated areas (see Figure 5-9A). A 2010 multiple increment sample from this area (SSFDRNG06) had a reported lead concentration of 162 mg/Kg, which is lower than the MCP Method 1 S-1/GW-1 Standard for lead.

- E Range - The average concentration of lead in the two multiple increment samples from Area 4/South (2006 sample location SSER4S5001 – the embankment at the back of the range) exceeded 300 mg/Kg. The average concentration of nitroglycerin in multiple increment samples collected from Area 1/Center exceeded the calculated MCP Method 2 S-1 standard for those samples analyzed by explosives Method 8330, but the corresponding multiple increment average calculated using the results from the samples analyzed by SVOC Method 8270 was well below this value. The various areas for E Range are shown in Figure 5-10B.

- G Range - The average concentration of 2,4-DNT (0.74 mg/Kg using SVOC Method 8270) in Area SS128A-SS128D slightly exceeds the Method 1 S-1/GW-1 Standard (0.7 mg/Kg), but is below the MCP Method 2 S-1 Standard (2.0 mg/Kg). The 2013 multiple increment sample results for antimony and lead for Area 1A (corresponding to the footprint of GR01A, see Figure 5-12B) exceeded their respective MCP Method 1 S-1/GW-1 Standards. A 2006 performance evaluation sample (SSGRS01) from Area 1A also exceeded the MCP Method 1 S-1/GW-1 Standard for lead.

- GB Range - The average concentration of dieldrin in the discrete/composite samples collected from Area 4A (which corresponds to the footprint of the 2013 multiple increment sample GAR04A) exceeded the Method 1 S-1/GW-1 Standard due to a single detection in sample SS143X, (see Figure 5-13B).

- H Range - The average concentration of lead in the discrete/composite samples from the area of SS160A-SS160C (see Figure 5-14B) exceeded its Method 1 S-1/GW-1 Standard. All of the samples used to calculate this average were collected in 2002. More recent data from this area is not available.

- K Range - The average concentrations of lead in multiple increment samples from the areas Behind Targets 1&2 and Range Floor 5&6 (see Figure 5-17C) exceed the MCP Method 1 S-1/GW-1 Standard for lead. A single discrete/composite 2006 performance evaluation sample from the area Range Floor 3&4 slightly exceeded the MCP Method 1 S-1/GW-1 Standard for lead (304 mg/Kg versus 300 mg/Kg). The average concentration of nitroglycerin in multiple increment samples collected from Firing Line 2 exceeded the calculated MCP Method 2 S-1 standard for those samples analyzed by explosives Method 8330, but the corresponding multiple increment average calculated using the results from the samples analyzed by SVOC Method 8270 was well below this value.

- KD Range (East) - The average concentrations of chromium (total) and dieldrin in discrete/composite samples from Area 44A exceed their respective MCP Method 1 S-1/GW-1 Standards (see Figure 5-18B). These samples were collected in 1999 from

three depth intervals at a single location. More recent data from this area is not available.

- Former M-2 Range - The concentration in several multiple increment samples for lead exceeded the MCP Method 1 S-1/GW-1 Standard for lead. These include samples from Areas 2, 3, ARM2/ 4, and 5 (see Figure 5-25B).

- N Range - The 2013 multiple increment samples for lead from Areas 1 and 2 (corresponding to the footprints of NR01A and NR02A, see Figure 5-28B) exceeded its MCP Method 1 S-1/GW-1 Standard. There were no previous samples collected from this area.

- Former N Range - The 2013 multiple increment sample for lead from Area 1 (corresponding to the footprint of SSFMRN01, see Figure 5-29) exceeded its MCP Method 1 S-1/GW-1 Standard. There were no previous samples collected from this range.

- SE Range - The average concentration of nitroglycerin in discrete/composite samples collected from areas SE Area, SE Area 1, SE Area 3, and SE Area behind Firing Line (see Figure 5-34B) exceeded the calculated MCP Method 2 S-1 Standard. All of these averages were calculated using sampling results for samples that were analyzed by explosives Method 8330. The average concentration of nitroglycerin in multiple increment samples collected from SE Area 2 exceeded the calculated MCP Method 2 S-1 Standard for those samples analyzed by explosives Method 8330, but the corresponding multiple increment average calculated using the results from the samples analyzed by SVOC Method 8270 was well below this value.

- Succonsette Pond - The average concentration of cadmium in discrete/composite samples collected in 2002 Area 1 (8.5 mg/Kg) is greater than the Method 1 S-1/GW-1 Standard (which is based on background), but is below the Method 2 S-2 and S-3 Standard (30 mg/Kg). A 2013 multiple increment sample from this area was well below the Method 1 and Method 2 Standards. The locations of discrete/composite samples are shown on Figure 5-37A. The locations of the 2013 multiple increment samples are shown on Figure 5-37B.

- SW Range - The average concentration of nitroglycerin in multiple increment samples collected from SW Area 2 (see Figure 5-34B) exceeded the calculated MCP Method 2 S-1 Standard for those samples analyzed by explosives Method 8330, but the corresponding multiple increment average calculated using the results from the samples analyzed by SVOC Method 8270 was below the Standard.

- T Range - The average concentration of lead in discrete/composite samples from Area 1 exceeds the MCP Method 1 S-1/GW-1 standard (see Figure 5-38B). These samples were collected in 2002 from along the Firing Line. The average concentration of lead in more recent multiple increment samples from this area was just below the MCP Method 1 S-1/GW-1 Standard, although a number of individual multiple increment samples (35) exceeded the Standard. The average concentration of chromium in multiple increment samples from several areas (i.e., Area 1, Area 2, Area 3C, Area 3E, and Area 3W - see Figure 5-38B) at T Range is greater than the Method 1 S-1/GW-1 Standard,

but the elevated chromium levels have been attributed to the grinding procedure previously used for the preparation of collected samples for analysis.

With the exception of two samples (5,800 mg/Kg at SS169A from T Range and 3,850 mg/Kg at GR01A from G Range), the maximum detected concentrations of lead at each of the ranges evaluated is below the MCP Upper Concentration Limit (UCL) value of 3,000 mg/Kg. The maximum detected concentration of cadmium at Succonsette Pond (30.9 mg/Kg) is below the cadmium UCL (i.e., 300 mg/Kg). The maximum detected concentrations of chromium at KD Range (East) and at T Range are below the chromium UCL value of 2,000 mg/Kg. The maximum detected concentrations of dieldrin at Former B Range and KD Range (East) are below the dieldrin UCL of 20 mg/Kg. The maximum detected concentration of 2,4-DNT at G Range is below its UCL value of 700 mg/Kg. The maximum detected concentration of antimony at G Range is below the antimony UCL of 300 mg/Kg. There is no published MCP UCL for nitroglycerin.

Table E.1
Summary of Ranges with MCP Method 1* Exceedances

Range	Analyte	Area Descriptor	Sample Type	Frequency of Detection	Number of MCP Method 1 S-1/GW-1 Exceedances	Maximum Detected Concentration (mg/Kg)	Average Concentration (mg/Kg)	MCP Method 1 S-1/GW-1 Standard (mg/Kg)	MCP Method 2 S-1 Standard (mg/Kg)
B RANGE	CHROMIUM, TOTAL	MIS 1	MIS	0 / 1	0	Not Detected	Not Applicable	30	30
		MIS 2	MIS	0 / 3	0	Not Detected	Not Applicable	30	30
		MIS 3	MIS	0 / 1	0	Not Detected	Not Applicable	30	30
		456	Discrete/Composite	2 / 2	0	6.2	6.05	30	30
		456	MIS	28 28	0	10.8	5.04	30	30

Prepared for Massachusetts Army National Guard

ABSTRACT

Environmental issues for small arms training with lead projectiles are examined in this report for Camp Edwards located at the Massachusetts Military Reservation (MMR), in order to evaluate whether past or future use of lead in small arms has or will result in lead mobilization to groundwater. A review of relevant literature and case studies demonstrates lead is toxic to humans and wildlife and, therefore, exposure must be minimized. The literature also demonstrates lead mobilization occurs chiefly by wind and surface water erosion, generally not by dissolution and leaching through soil. Environmental conditions at Camp Edwards dictate that wind and surface water are not primary avenues of transport, due to extensive vegetative cover and highly permeable soils. Highly permeable soils limit corrosion of metallic lead but also can facilitate transport for dissolved forms of lead. Because highly permeable soils favor transport, a careful analysis of the geochemical conditions with respect to lead vertical transport to groundwater was a focus for this study. It is the conclusion of this study that, lead has not contaminated the groundwater in any significant way based on the absence of lead plumes and only one groundwater monitoring well associated with the small arms ranges had a single low lead detection < 2 ppb. In addition, this conclusion is supported by a careful analysis of the geochemistry of lead and conditions under which lead is mobile as well as site-specific data. Specifically, Camp Edwards has

1. Soil conditions that are not sufficiently acidic to readily dissolve metallic lead,

2. High soil permeability, low chloride and soil resistivity of surface soils, conditions not favorable for the rapid corrosion of lead,

3. High degree of lead adsorption based on non site-specific column studies as well as site-specific soil profiles, unsaturated zone monitoring, and aquifer studies, and

4. Depth to groundwater more than 30m in those areas where training is to be resumed.

Recognizing both the lack of sufficient data to quantify the ability of Camp Edward's soils to immobilize lead, knowing the soil's ability to immobilize lead is finite, and given its toxicity, range design and maintenance programs to limit lead exposure are prudent. Although these activities are not addressed in this document, they will be addressed in the range specific pollution prevention plans. Minimizing erosion and surface water runoff is a necessary step for preventing environmental exposure. Other measures to consider, include, but are not limited to periodic removal of metallic lead particles from ranges and backstop-berms, and addition of treatment agents highly effective for immobilizing lead.

It is important to emphasis this evaluation was based upon information readily available through literature and site specific information. This study contains recommendations for additional studies which would help further refine these conclusions. However, these studies would be useful for the ongoing monitoring of range operations.

PREFACE

This report was prepared by Jay L. Clausen, Biogeochemical Sciences Branch (BSB), U.S. Army Engineer Research and Development Center (ERDC), Cold Regions Research and Engineering Laboratory (CRREL), Hanover, New Hampshire.

The U.S. Army Environmental Center provided funding for this work.

Dr. Thomas Douglas, BSB, CRREL-Alaska and Dr. Anthony Bednar Environmental Laboratory provided technical reviews.

This report was prepared under the general supervision of Terrence Subecki, Branch Chief, BSB, CRREL; Dr. Lance D. Hansen, Deputy Director, CRREL; and Dr. Robert E. Davis Director, CRREL.

The Commander and Executive Director of the ERDC is Colonel Richard B. Jenkins. The Director is Dr. James R. Houston.

EXECUTIVE SUMMARY

Purpose

Military testing and training ranges are vital for preparing military troops for combat and maintaining readiness. There are increasing concerns that a reduction in United States (US) military readiness will result if training range usage is restricted. Nonetheless, range managers must balance range activities so training can proceed without the environmental consequences associated with repeated release of undesirable residues. The objectives of this study are to provide the Massachusetts Army National Guard (MAARNG) an assessment of the fate of lead on the small arms ranges (SARs) at Camp Edwards. The principal question considered is whether resumption of training with lead projectiles will have an undesirable environmental impact such as vertical migration to groundwater (> 30 m) underlying the training ranges. The approach for satisfying the objective consists of 1) general assessment of the geochemistry of lead and identification of conditions where lead migration is favorable, 2) description of the geochemical conditions at Camp Edwards and whether the environment is conducive for lead migration, and 3) evaluation of existing lead data at Camp Edwards focusing particularly on data available from the SAR.

Small Arms Ranges

The configuration of a SAR consists of 1) a firing point where the soldier fires the weapon, 2) the range floor, down range from the firing point, 3) targets which can be located on the floor or at the end of the range, and 4) typically a primary berm backstop located behind the targets. Over the last decade, SAR design has evolved to incorporate range sustainability concepts such that berms serve both a safety and environmental function by concentrating the lead in a small area. The height of the berm can vary from a few meters up to 10 m. Sometimes a trough to collect surface water runoff is located at the base on the front side of the berm.

Once a projectile ejects from the bore of the weapon, it travels towards the target. Because of scouring of the projectile in the weapon barrel, a small amount of copper (if the bullet is copper-jacketed) and/or lead (unjacketed projectile) may be deposited near the firing point. In addition, small quantities of propellant powder and lead styphnate used in the primer may also be released. On SARs where a primary berm backstop exists, the projectile impacts the berm in a heads-on manner. The two mechanisms at work to scrub energy to stop the projectile are displacement of soil particles and fragmentation. Eventually, all of the energy is dissipated, and the projectile comes to rest.

The lead within the berm is subject to wind and water erosion and corrosion/dissolution processes. At Camp Edwards, surface water runoff or overland flow is usually unimportant because of the coarse soil texture and high soil permeability. Corrosion processes are also relatively slow at Camp Edwards because the coarse soils limit ponding and are low in chloride.

Although some shotgun training will occur; in general, the projectiles used are thought to result in mostly large fragments having a relatively small surface area thereby further limiting corrosion/dissolution. Nonetheless, all projectiles are abraded to some extent such that some small, high-surface area particles will also be present. Thus, as the lead content in the surface soil increases, removal activities may be prudent. MAARNG plans to manage the lead by performing best management practices as outlined in the Pollution Prevention Overview (Small Arms Range Supplement) which follows US Army guidelines.

Ecological receptors of concern at shooting ranges include invertebrates, fish, mammals, and birds. Although rifle ranges have been implicated in certain studies where lead toxicity has been observed, nearly all confirmed examples of harm to terrestrial species are with lead shot. The highest risks have been predicted for small mammals and birds ingesting lead shot incidentally while feeding or intentionally as grit. Research has demonstrated mortality for some small mammals and birds may result from the ingestion of a single lead pellet. Similar to shot, lead abraded from a bullet is immediately available for transport by water and wind and for bioaccumulation, but many rifle projectile fragments are too large for ingestion. For example, one investigation reported only 1.5% of a 22-caliber non-jacketed bullet was abraded when fired into a bucket of sand. In addition, research has shown large fragments are relatively stable - within 6 to 13 years, only 5 to 17% of metallic lead was corroded in lead shotgun pellets and after a period of 20 to 25 years, an average of only 5 to 16% of metallic lead in pellets had been transformed to lead carbonates ($PbCO_3$ and $Pb_3(CO_3)_2(OH)_2$) and lead sulfate ($PbSO_4$). The size of the particles is a function of the caliber of the projectile as well as the soil type, i.e. coarser soils result in finer lead particles and greater smearing onto soil. Finally, the distance to the target will also affect the particle size because the velocity/momentum at impact will decrease with distance.

Lead Geochemistry

Lead is a relatively immobile element in the terrestrial environment. Soils may have solutions supersaturated with respect to cerussite ($PbCO_3$), hydrocerussite ($Pb_3(CO_3)_2(OH)_2$), lead oxide $Pb(OH)_2$, lead phosphate $Pb_3(PO_4)_2$, lead hydroxyapatite $Pb_5(PO_4)_3(OH)$, and lead oxyphosphate $Pb_4O(PO_4)_2$. Lead phosphate minerals, in particular, are so sparingly soluble, thermodynamic data predicts these phases will control dissolved lead in soil solution under the geochemical conditions commonly found in natural systems. Under reducing conditions in which sulfate is reduced to sulfide, lead may be sequestered in galena (PbS), which has a solubility in natural waters too low to measure by conventional technology. Consequently, under the normal range of soil pH and redox conditions, aqueous lead concentrations should generally be limited to low parts-per-billion levels, through precipitation reactions.

In addition to forming a range of stable mineral phases in both oxygen-rich and oxygen-poor environments, lead can bind to mineral surfaces directly and can from adsorption complexes on

surfaces of quartz, humus, iron oxides, aluminum oxides, manganese oxides, and virtually any mineral with oxygen or sulfur atoms at the surface.

Localized regions with potentially high lead levels will be present at firing ranges at lead accumulation areas or adjacent to corroding lead particles. Any elevated dissolved lead however, is expected to remain localized because sparingly-soluble mineral precipitates will form or the lead will be adsorbed onto the soil matrix. Consequently, in highly contaminated soils, aqueous lead levels may be elevated in or near the location where deposition occurred.

Camp Edwards Characteristics

Camp Edwards surface soils are coarse-grained and typically classified as sandy loams and loamy sands. These soils permit rapid recharge of percolating water and facilitate air exchange with the atmosphere. Recent samples from several SAR impact berms were evaluated for soil pH which ranged from 6.2 to 7.4 with a median value of 6.5. Total organic carbon levels across the site range from 31 to 247,000 mg/kg, with a mean of 11,050 mg/kg. A few soil horizons have a more developed organic layer present but in most locations, an organic-rich surface soil is absent. Clay-sized particles (traces in most samples) and cation exchange capacity (8 to 10 meq/100g), factors affecting sorption processes, are low in the surface soils and lower still in deeper soils. Finally, soils have low concentrations of soluble salts (e.g. base cations such as calcium and magnesium as well as sodium and chloride) because these ions have been removed by leaching. Taken together, these characteristics yield an environment in which leaching of dissolved species can occur rapidly although the corrosion potential for metals is relatively low. Nevertheless, the most significant factors with respect to lead remain its propensity to form sparingly soluble precipitates and to adsorb to relatively inactive surfaces such as pure quartz.

The small arms training ranges lie directly over the Sagamore Lens, a major groundwater recharge area and the most productive portion of the Cape Cod Aquifer. The apex of the Sagamore Lens is located at the southeast corner of the Impact Area from which groundwater flows radially in all directions. The thickness of the unsaturated zone varies from 18 to 37 m across most of the area with 30 m being typical for the SARs. Surface water runoff is limited to a few hundreds of meters at most because of the highly permeable nature of the sand and gravel underlying the area.

Camp Edwards Data

Over 9,000 soil samples have been collected and analyzed for lead across Camp Edwards to date. These data indicate an overall sporadic distribution pattern but elevated levels do coincide with the firing lines and target areas of the SARs. However, little or no migration to the subsurface is evident. The locations (firing lines, targets) where lead is highest are consistent with firing range data obtained elsewhere. The maximum concentrations at Camp Edwards

(~12,000 mg/kg), however, are lower than have been reported at many other military installations probably because larger lead fragments were physically removed, in 1999 as part of the Lead Berm Maintenance Project.

Many Camp Edwards samples with elevated lead have been subject to the Toxicity Characteristic Leaching Procedure (TCLP) - a test to determine whether the sample is hazardous under the Resource Conservation and Recovery Act. In general, TCLP-lead concentrations were greatest in the upper 1 m of the berm face, a finding consistent with the presumed penetration depth of small caliber projectiles. Based on this finding, several SARs in 1999 were selected for a treatment process consisting of the application of a liquid reagent – Maectite - a phosphate developed to chemically bond to lead within the soil matrix creating geochemically stable precipitates. Several thousand cubic meters of soil were also removed. Subsequent monitoring of soil pore water underneath these treated areas indicates no significant migration of dissolved lead.

Thirteen additional monitoring wells were installed in the fall of 2006 downgradient and near the berm face for several SARs. These wells have been sampled twice since installation and to date have had no consistent reportable lead detections. There is only one groundwater monitoring well (MW-72S) associated with the SARs with a single low detection – ppb range. These results indicate lead has not migrated to groundwater at the maintained ranges that have been monitored, including two at which training with lead ammunition began in 1935.

Finally, several modeling approaches have been used to evaluate lead mobility at Camp Edwards. Modeling of lead is problematic because of the difficulty of predicting corrosion and of including precipitation reactions. Indeed, modeling to date has conservatively assumed complete dissolution and has ignored precipitation. Nevertheless, the models predict the time for lead to migrate from the surface to the water table is several hundred centuries.

Conclusions

This report has assessed the fate of lead released into the environment at Camp Edwards from firing at SARs. The principal conclusions are; corrosion and dissolution processes are sufficiently slow and mechanisms for attenuation, such as precipitation and adsorption, sufficiently robust, that lead has not migrated to groundwater. These conclusions are supported by the following facts:

1. Multiple soil profile samples collected prior and post-berm maintenance from six SARs indicated little vertical migration of lead,

2. Geochemical conditions within the surface soils, (e.g. pH, chloride, resistivity, permeability, and oxygen) are not conducive for significant corrosion, dissolution, and transport of lead,

3. Experimental results from other studies with conditions similar to Camp Edwards showed minimal lead movement,

4. Experimental results from other studies consistently demonstrate such high and variable measurements for lead partition coefficients that modeling exercises typically have uncertainties on the order of centuries in their predictions,

5. Geochemical studies found in the literature suggests the propensity to form sparingly soluble precipitates, and not sorptive capacity, may be the most important factor controlling lead migration in the subsurface,

6. The corrosion/dissolution rate, although qualitatively predicted to be slow, cannot be quantified because of several uncertainties ranging from uncertainty regarding the particle size distribution to the effects of wet/dry cycles,

7. Unsaturated zone modeling using two different software codes predicted the vertical migration of lead would take centuries to reach groundwater,

8. Water samples from most monitoring wells (except MW-72S) installed immediately downgradient of the backstop berms at a number of SARs showed no measurable lead,

9. Groundwater data collected to date from across Camp Edwards demonstrated little to no lead contamination as a result of accumulation from small arms training, despite lead being continuously released to soil for more than 60 years,

10. Tracer studies conducted by the US Geological Survey near Camp Edwards demonstrated an aqueous form of lead was rapidly adsorbed onto the soil, implying the same reactions will attenuate lead movement in the unsaturated zone, and

11. Lead introduced into the groundwater near Camp Edwards in a sewage treatment effluent was rapidly and completely attenuated.

The technical literature, however, clearly describes dangers to humans and wildlife exposed to lead. Although lead mobility is limited at Camp Edwards, the data collected to date is inadequate to quantify the amount of lead that can be safely deposited in the environment. It is important, therefore, to minimize environmental exposure through the application of best management practices.

1.0 Introduction

Military testing and training ranges are vital for preparing military troops for combat and maintaining readiness. There are increasing concerns that a reduction in United States (US) military readiness will result if training range usage is restricted. Nonetheless, range managers must balance range activities so training can proceed without the environmental consequences associated with repeated release of undesirable residues.

US Army/National Guard soldiers have trained with small arms ammunition containing lead on Cape Cod since 1908, and specifically at Camp Edwards since its opening in the mid 1930's until 1997. In 1997 the U.S. Environmental Protection Agency (USEPA), through Administrative Order #2 (AO2), banned training with lead projectiles at Camp Edwards due to concerns about lead mobility. Consequently, training with a tungsten/nylon projectile (5.56 millimeter [mm]) began in 1999. In February 2006, the Massachusetts Army National Guard (MAARNG) discontinued training with the tungsten/nylon projectile because of concerns about tungsten's environmental mobility and unknown toxicity. These circumstances have resulted in an inability of National Guard units to perform qualification testing as part of their training. Consequently, the MAARNG has commissioned this study to assess the environmental consequences of resuming training with lead projectiles at Camp Edwards.

Moreover, the MAARNG desired identification of engineering controls effective at eliminating migration of lead from the small arms training ranges. An example of a successful project of this type occurred in 1998 under MAARNG and the Impact Area Groundwater Study Program (IAGWSP) in response to AO2. Soil was removed from the small arms range (SAR) berms and large metallic lead fragments were separated using a soil washing technique. The soil was then treated with Maectite^{TM}, which bound up any dissolved lead into a sparingly soluble lead phosphate complex, and the treated soil was placed back on the berm.

1.1 Objective

The objectives of this study are to provide MAARNG an assessment of the fate of lead on the SARs at Camp Edwards, i.e. will lead have an undesirable environmental impact such as vertical migration of lead away from those SARs located over deep (> 30 meters [m]) groundwater. The methodology for meeting the objective consists of 1) general assessment of the geochemistry of lead and identification of conditions where lead migration is favorable, 2) description of the geochemical conditions at Camp Edwards and whether the environment is conducive for lead migration, and 3) evaluation of all existing lead data at Camp Edwards focusing particularly on data available from the SARs.

1.2 Small Arms Ranges

The purpose of a SAR is to allow training with weapons of a small caliber, i.e. handgun, rifle, shotgun, or machine gun. The distance from the firing point to the target can vary from 10 to 1,000 m. The layout of SARs consists of several different configurations depending on the training intent.

The configuration of a SAR consists of a firing point where the soldier fires the weapon. Down range from the firing point is the range floor. The targets can be located on the range floor or near the end. In some configurations, such as known distance ranges, the targets are located in a line spanning the width of the range. This layout typically has a primary berm backstop, originally installed for safety purposes, located behind the targets. Over the last decade, SAR design has evolved to incorporate range sustainability concepts such that the berm serves both a safety and environmental function by concentrating the lead in a small area. The past practice for berm construction involved material scraped from the range floor, although materials can be brought in from elsewhere. The height of the berm can vary from a few meters up to 10 m. Sometimes a trough to collect surface water runoff is located at the base of the front side of the berm. Another layout has a series of pop-up targets located at varying distances. In either configuration, the range is orientated in such a manner that the projectiles travel towards an impact area.

1.3 Conceptual Model

Small arms' firing introduces lead projectiles, other projectile-related metals (e.g. copper), and propellant residues into the environment. Most of the ammunition fired on military SAR consists of a steel penetrator followed by the lead/antimony slug, with a propellant cartridge and ignition cap on the end with the entire assembly jacketed with a copper alloy. The copper alloy consists of copper, lead, and zinc, which are used in the jacket as well as cup primer and case (MIDAS 2007). The ignition cap contains compounds of antimony, barium, lead (lead styphnate), and potassium.

Not all small arms projectiles have a copper jacket such as some pistol and shotgun cartridges which contain bare slugs or balls. Copper-jacketed projectiles are used in high-velocity and automatic weapon systems. Projectiles can be solid such as the lead/antimony core or filled with tracer or incendiary materials. Tracers are used to determine the direction of fire and contain barium, magnesium, potassium, strontium, and zinc compounds (MIDAS 2007). Perchlorate is also used in some tracer rounds such as the .50 cal and could be released at the firing point, range floor, and impact berm.

Once the projectile ejects from the bore of the weapon, it travels towards the target. Because of scouring of the projectile in the weapon barrel, a small amount of copper and/or lead (unjacketed projectile) may be deposited near the firing point. Small quantities of propellant and lead styphnate used in the primer (MIDAS 2007) may also be released. Propellant constituents include nitroglycerin, nitrocellulose, dibutyl phthalate, and diphenylamine (MIDAS 2007). The first three compounds may be released at the firing point. Diphenylamine is an unstable compound and upon exposure to soil will oxidize to form N-nitrosodiphenylamine. Ideally, the projectile should travel straight along the firing lane to the target, where it is deposited intact (or nearly so) into the primary berm backstop. However, projectiles can miss the target but still hit the berm. In some cases, a projectile may hit the berm face and be deflected or in rare instances, may miss the berm entirely.

On SARs where a primary berm backstop exists, the soldier faces the berm and the projectile impacts the berm in a heads-on manner. Most constructed berms, including those at Camp Edwards, are made of soil derived from the installation or of sand and gravel. The two mechanisms at work to scrub energy to stop the projectile are displacement of soil particles and fragmentation. In sandy soils, displacement of soil particles allows a lead projectile to penetrate a meter or less into the berm. Eventually, all of the energy is scrubbed, and the projectile comes to rest, buried within the soil matrix.

Consequently, the working hypothesis is elemental lead may be found as particles attached to pieces of the bullet jacket, as pieces of intact slug material, or as small particles adhered to larger soil particles. Based on field reconnaissance, both intact projectiles with intact copper jackets as well as fragments of copper jacket material, steel penetrators, and chunks of lead can be found; however, a small quantity of fragments, too small to be readily-visible, are also produced. Once introduced into the environment, metallic lead oxidizes (rusts) resulting in the formation of lead salts on the metallic lead surface (Scheetz 2004). Rainfall encountering the lead salts dissolves a small portion, which can travel with the infiltrating water into the soil. The solubility of the salts is low, which limits mobility. Any remaining dissolved lead reacts with the soil matrix resulting in the precipitation of various less-soluble lead species and sorption of lead onto soil particle surfaces. The capacity of soil for lead sorption is not infinite, but in some cases, the mass of lead introduced into the environment and subsequently dissolved is negligible compared to the sorptive capacity of the soil. The only two studies found reporting lead in deep groundwater were the result of human introduction of lead directly to the groundwater following shock chlorination (Seiler 2006) or from the use of lead counterweights in water-level recorders (Kaste et al. 1999). Thus, lead migration typically is limited to a few meters in the vertical direction. In the case of Camp Edwards, the working hypothesis is soluble lead is immobilized under natural processes within a few meters of the soil surface.

In summary, Figure 1 (modified from Morton, undated) represents the processes by which lead could be mobilized at a SAR. At Camp Edwards, however, surface water runoff or overland flow is usually limited because of the coarse soil texture and high soil permeability, see Section 3. Similarly, the projectiles used and planned to be used in the future will result in mostly large fragments (Larson *et al.* 2006, Fackler 2007). Metallic lead will build up in surface soil or berm material with time, however, and removal activities may be necessary. MAARNG plans to perform best management practices to manage the lead, which are outlined in a Pollution Prevention Plan for Camp Edwards Small Arms Ranges (URS 2006) which follows US Army guidelines (USAEC 2005).

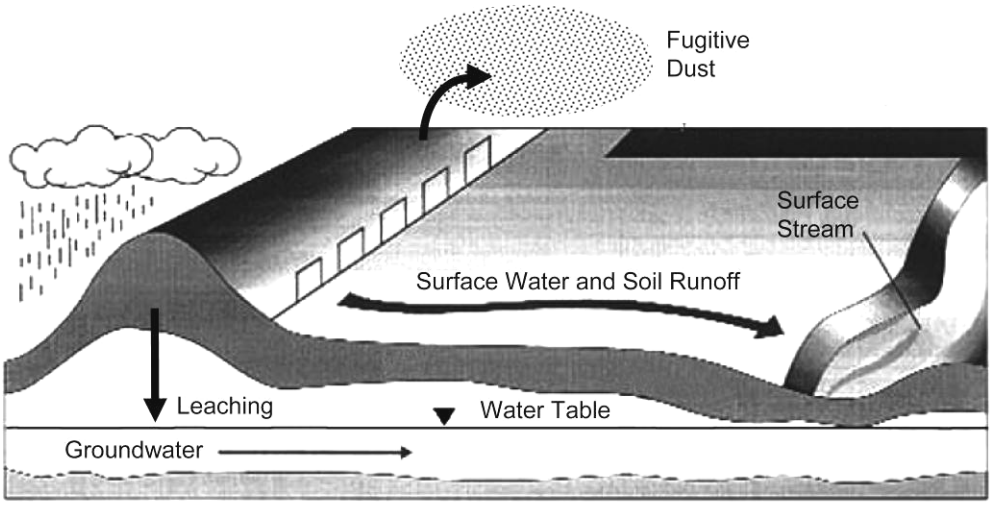

Figure 1. Conceptual site model of physical transport processes associated with a shooting range.

As will be discussed in Section 2.3.3 deposition of lead such as that introduced from firing small arms will result in immobilization within the soil through sorption processes.

1.4 Environmental Issues at Small Arms Ranges

Firing of projectiles at a SAR results in the introduction of metal to the environment. Typically, the primary environmental concern is with the introduction of metallic lead and the potential exposure to biota.

1.4.1 Lead Transport

The Sporting Arms and Ammunition Manufacturing Institute (SAAMI 1996), U.S. Air Force (USAF 1998), U.S. Army (USAEC 1998, 2005) and Interstate Technology and Regulatory

Council (ITRC 2003, 2005) have summarized the major geochemical processes affecting lead transport at shooting ranges as adsorption/desorption and precipitation/dissolution. The SAAMI report further concludes the relative influence of adsorption/desorption is approximately one order of magnitude (10 times) greater than precipitation/dissolution. Indeed, a review of these reports indicates lead transport occurs most easily by surface water and wind erosion and not by migration through soil. These processes and their relevance at Camp Edwards are discussed in detail in Sections 3 and 4. Surprisingly, very few published studies have evaluated the migration of lead in the soil profile and even fewer the migration to groundwater with the few conducted demonstrating limited lead movement. Numerous journal articles on lead research and lead reports make the statement that lead is problematic due to the potential migration of lead (Astrup *et al.* 1999, Craig *et al.* 2000, USEPA 2005a, Sorvari *et al.* 2006), however only a few studies demonstrate the limited movement of lead in the environment (Murray *et al.* 1997, Craig *et al.* 1999, Rooney *et al.* 1999, Cao *et al.* 2003a, Soeder and Miller 2003).

1.4.2 Toxicity

Lead is toxic to humans and wildlife because it affects the function and structure of a vertebrate's kidney, bone, central nervous system, and hematopoietic system and produces adverse biochemical, histopathological, neurophysical, fetotoxic, teratological, and reproductive effects (Eisler 1988, Schulz *et al.* 2006). For these reasons, the USEPA's action level for lead in water delivered to users of public drinking water systems is 15 micrograms per liter (µg/L) but the goal for lead is zero. The USEPA has also established 400 milligrams per kilogram (mg/kg) for lead in residential soils as a guidance value for protection of public health based on an analysis of the direct ingestion pathway for children. Presently, the Massachusetts Department of Environmental Protection (MassDEP), Method 1 S1/GW1 cleanup standard, applicable for sites state-wide with unrestricted use is 300 mg/kg. As discussed subsequently in this report, most uncontaminated soil contains less than 50 mg/kg, but soil lead levels and road and house dusts in many urban areas exceed 200 mg/kg or more (Fergusson and Kim 1991). The MADEP lists several different mean background values for Massachusetts soils, which range from 15 to 100 mg/kg (MassDEP, 2007).

Ecological receptors of concern at shooting ranges include invertebrates, fish, mammals, and birds. Typical risk assessments predict unacceptable levels of risk from lead for raptors, small (e.g. mice), and large (e.g. fox and deer) terrestrial mammals (Peddicord and LaKind 2000, USEPA 2003). The highest risks have been predicted for small mammals and birds ingesting lead shot incidentally while feeding or intentionally as grit (Peddicord and LaKind 2000). The predicted adverse effects on small mammals and birds are supported by the literature, which has shown mortality may result from the ingestion of a single lead pellet (Ma 1989, Roscoe *et al.* 1989, Hoffman *et al.* 2000, Vyas *et al.* 2000). Similarly, Hunt *et al.* (2006) reported that a minute

quantity of fragments dispersed in deer carcasses are highly-toxic to wildlife. Additional information is available from the USEPA ECOTOX database (USEPA 2003).

Waterfowl mortality due to the ingestion of lead shotgun pellets was documented as early as 1874. Additionally, large volumes of lead shot accumulate in terrestrial ecosystems such as shooting areas, firing ranges, and clay-pigeon shoots where they can be directly ingested by a range of terrestrial birds (Vyas *et al.* 2000, Lewis *et al.* 2001). Thus, studies that are more recent have examined terrestrial avian species. For example, of 157 doves fed 2 to 24 lead shot pellets, 104 died prior to the conclusion of the study while all 22-control doves survived (Schulz *et al.* 2006). Similarly, lead poisoning has been blamed for the loss of California Condors. A study of Condor mortality was unable to identify, with certainty, the source of lead but included military rifle ranges at Camp Roberts and Fort Hunter Liggett as possibilities (Fry 2003). In the latter instances, the proposed exposure route was through bioaccumulation. In other words, raptors feeding on rodents from lead-contaminated sites eventually consumed too much lead themselves. The study suggested other raptors are as susceptible to lead poisoning as are condors. A 1988 report by the U.S. Fish and Wildlife Service (USFWS 1988) documented lead poisoning in 31 avian species other than waterfowl while a more recent report raised the number to 59 (Fisher *et al.* 2006). The latter report notes, “While bans on the use of lead shot for hunting waterfowl will inevitably reduce the likelihood of poisoning of raptors that prey on or scavenge waterfowl, they do nothing to prevent the poisoning of raptors that feed on hunted species away from wetlands, or those that feed on a range of avian and mammalian prey.” Fisher *et al.* (2006) concludes, “It is clear that the only practical way of removing the risk of lead poisoning from ammunition to avian species is to replace the use of lead with non-toxic alternatives, for all hunting and other purposes, and in all habitats. Until this happens, large numbers of birds, some of which are already of unfavorable conservation status, will continue to die from lead poisoning.”

A study with respect to lead’s toxicity to plants has been mixed. ITRC (2005) has proposed methods for mitigating lead impacts to closed ranges and the U.S. military has been assessing methods to manage and cleanup SARs (USAEC 1998, 2005) due to lead’s toxicity to wildlife. One approach being evaluated, phytoremediation, involves the growth of plants which bioaccumulate lead (Fry 2003). Greenhouse studies indicate plants could accumulate significant lead (Behel *et al.* 1998) but field studies have been inconclusive. Apparently, sub-optimal growing conditions on most ranges and the relatively low bioavailability of particulate lead significantly inhibit bioaccumulation in plants (Fry 2003). Limiting vegetative bioaccumulation may be a viable approach for minimizing lead exposure to ecological receptors.

1.4.3 Environmental Exposure

Although rifle ranges have been implicated in certain studies where toxic effects from lead have been observed, nearly all confirmed examples of harm to terrestrial species are with lead shot. Similar to shot, lead abraded from a bullet is immediately available for transport by water and wind and for bioaccumulation, but rifle projectile fragments are most likely too large for ingestion. Several studies have been conducted looking at grit uptake of birds and found that the size of grit selected is a function of the size of the bird. In general, birds prefer grit sizes less than 2 mm (Trost 1981, Pain 1990, Stafford *et al.* 1996, Peddicord and LaKind 2000). Hardison *et al.* (2004) reported only 1.5 percent of a 22-caliber non-jacketed bullet was abraded when fired into a bucket of sand. In addition, much research has shown large fragments are relatively stable. For example, within 6 to 13 years, only 5 to 17% of metallic lead was transformed in lead shotgun pellets (Jorgensen and Willems 1987) and after a period of 20 to 25 years, an average of only 5 to 16% of metallic lead in pellets had been transformed to lead carbonates ($PbCO_3$ and $Pb_3(CO_3)_2(OH)_2$) and lead sulfate ($PbSO_4$) (Lin *et al.* 1995). A large proportion of the fragments found on military SARs are typically larger than pellets and jacketed with copper (Clausen personal observation), however sand size particles and smaller can be found (Larson et al. 2006). The degree of projectile fragmentation and size of particles is likely a function of the caliber of the projectile, velocity of the fired projectile, distance to the target, as well as the soil type. Coarser soils result in finer lead particles and greater smearing onto soil particles (Larson *et al.* 2006) whereas higher projectile velocities and shorter distance to the target results in greater fragmentation (Fackler 2007).

2.0 Background

2.1 Site Location

The Massachusetts Military Reservation (MMR) is an approximately 22,000-acre facility located in the towns of Bourne, Falmouth, Mashpee, and Sandwich in Barnstable County, Massachusetts. The reservation is divided into two main installations: Camp Edwards, which is controlled by MAARNG, and Otis Air National Guard Base which is controlled by the Massachusetts Air National Guard and USAF. Other, smaller installations at MMR include the U.S. Coast Guard Air Station Cape Cod, Cape Cod Air Force Station (PAVE PAWS radar), and the Massachusetts National Cemetery.

Camp Edwards encompasses approximately 15,000 acres of land. The training areas include numerous active and inactive ranges, training sites, and a centrally-located artillery, mortar, and rocket impact area. Soldiers currently practice maneuvering exercises, bivouacking, and SAR training with the southern cantonment area comprised of a complex of administrative offices, maintenance and training facilities, troop housing, and other support facilities.

2.2 Massachusetts Military Reservation Range Use History

The National Guard has been training since approximately 1908 on the Cape. In the 1940s, the installation was created and activated by the U.S. Army and used to train and deploy troops during World War II. The reservation was transferred to the Department of the Air Force after the Korean War and in the 1970s, the Army National Guard assumed operational control of Camp Edwards.

Historical use of ranges at Camp Edwards has been dictated by readiness needs for military forces and law enforcement agencies. The functions and use patterns of the training ranges over the years have varied to satisfy those needs. Many ranges have consequently been used for more than one type of training. Through a detailed search of archival information on historical range use, 34 sites at Camp Edwards were identified as having been used at one time or another for small arms training (USACE 1999a, 1999b, 2000). Subsequent reviews of range control records and site inspections revealed 17 of these ranges are still available for small arms training. In general, the modern, currently available SARs are positioned around the perimeter of the Impact Area with range fire directed inward towards the Impact Area (Figure 2). Each SAR has an associated surface danger zone (SDZ) which is an exclusion area identified to protect personnel from weapons firing during training. The SDZs on Figure 2 represents an area were a bullet, a bullet fragment or a ricochet could travel once fired. The SDZ represents a worse case scenario used for primarily for safety purposes in planning simultaneous operations

or activities in the range and training area. The SDZ represents the highly unlikely, however still possible, area which a bullet could travel once fired from a range. The SDZs do not account for containment systems, such as bullet traps, that may be on a SAR. Figure 3 shows the location of the SARs at Camp Edwards. The focus of this document is on those SAR available for training and does not include the Otis Fish and Game Ranges.

In response to changes in small caliber weapon systems use, SAR design at Camp Edwards has varied considerably over the decades. Modern range components, in general, include a level cleared range floor bordered by an up-range firing point and a downrange target line and earthen berm backstop constructed as a collection point for spent munitions. The number of firing positions along the firing point (which can be slightly elevated above the range floor) varies depending on the overall size of the range. Most of the available ranges also include a range control tower and target construction and repair facility. Many of the early SAR designs took advantage of natural topography and used hillsides as backstops rather than constructed berms.

Records indicate weapons used in small arms training at Camp Edwards have included pistols, rifles, machine guns, and shotguns with a variety of ammunition types fired. Rounds used in current outdoor training exercises are limited to plastic and blank ammunition. Future use of lead ball ammunition will likely include firing of 5.56, 7.62, and 9 mm, and .50 caliber projectiles as well as 00 Buckshot. Physical descriptions and use histories for each of the current and former SARs at Camp Edwards are presented in Table 1.

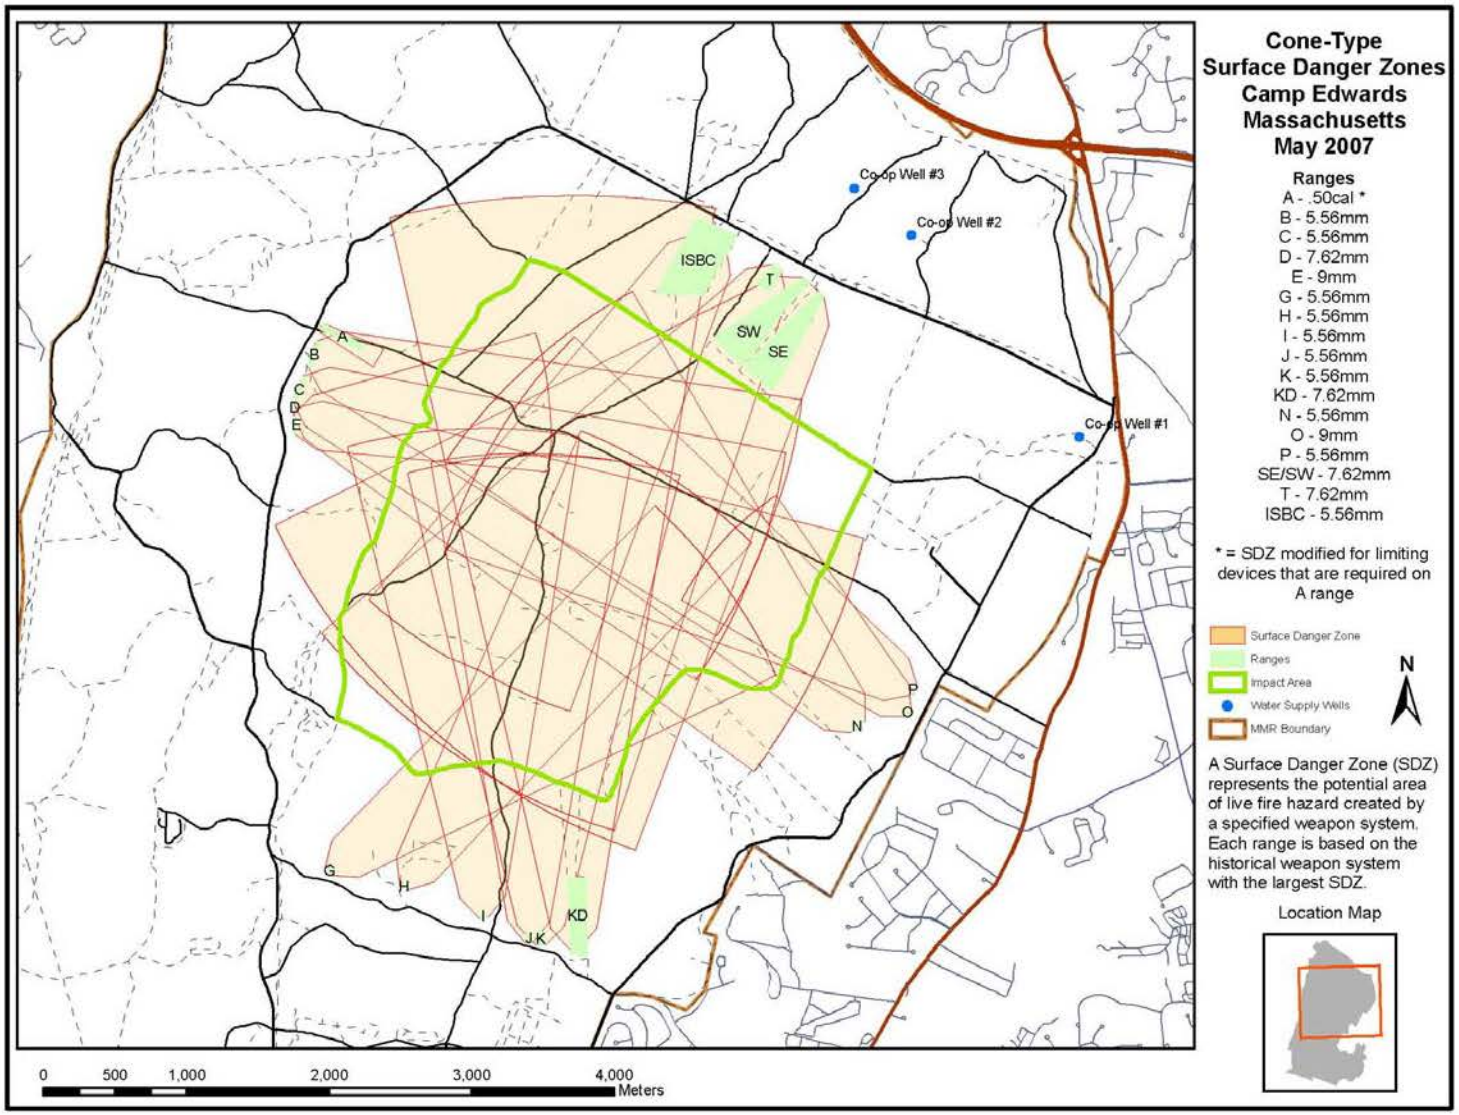

Figure 2. Small arms training range surface danger zones at Camp Edwards.

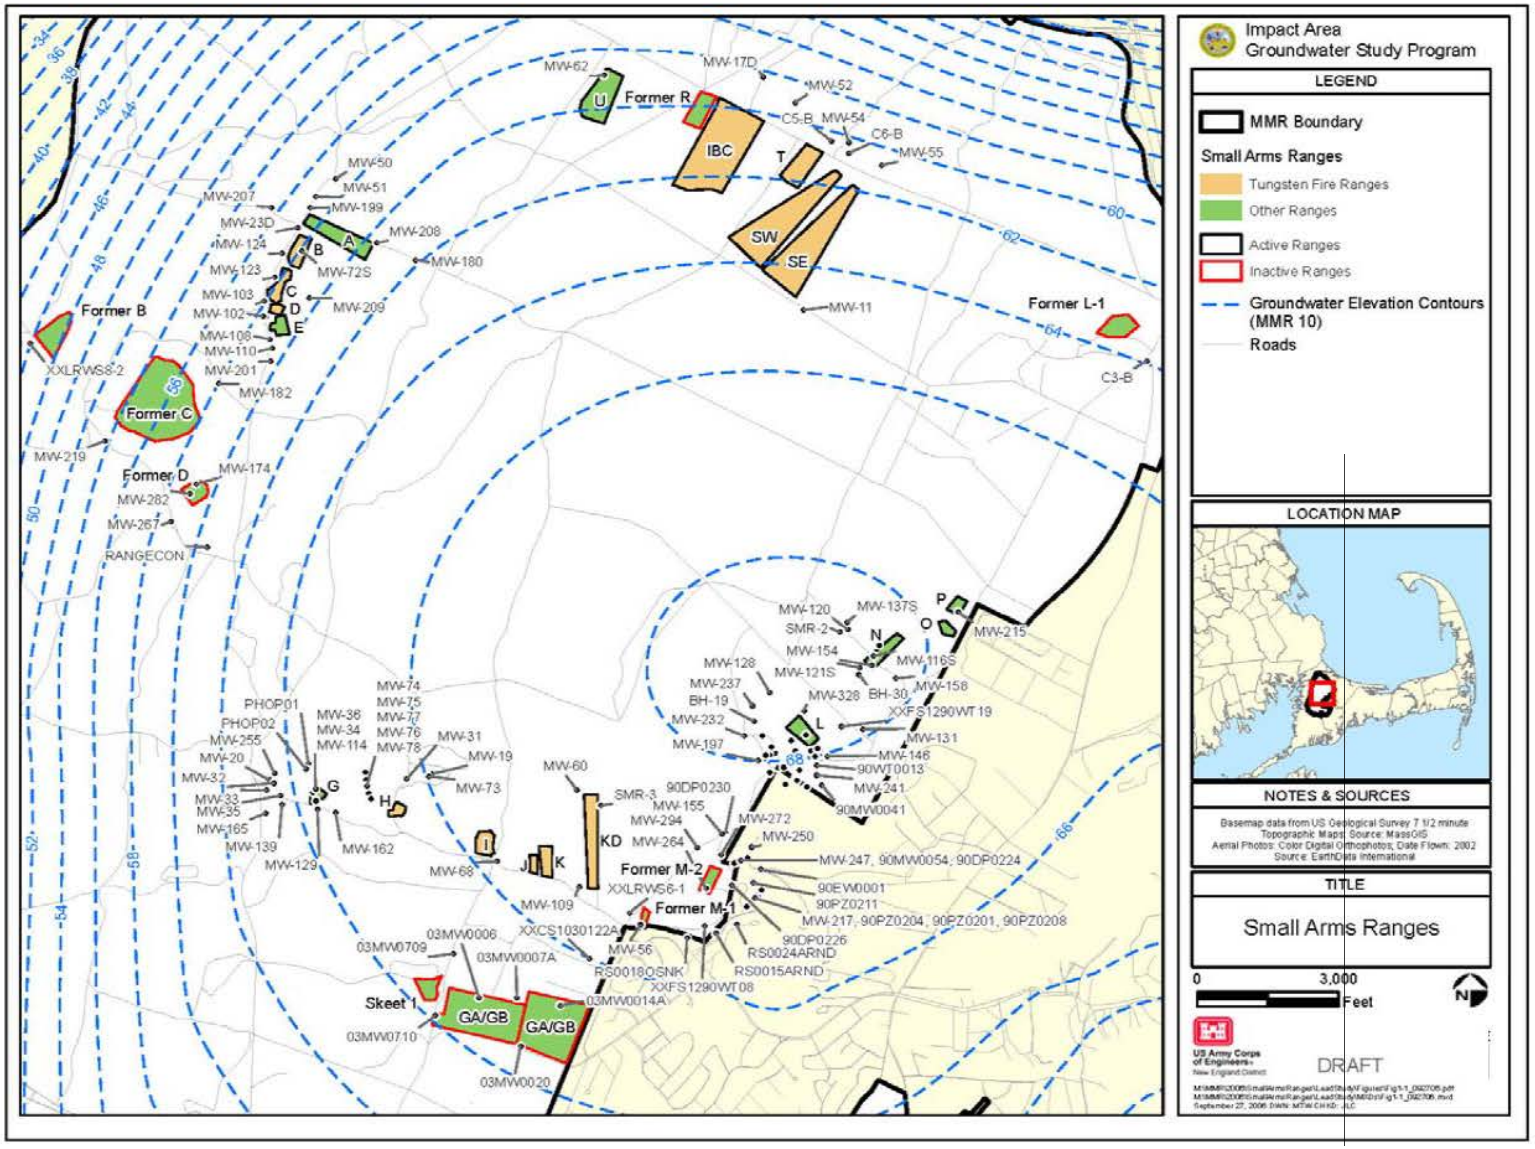

Figure 3. Small arms training ranges at Camp Edwards.

Table 1. Camp Edwards small arms ranges.

Range Name	Location	Period of Use	Training Activity	Authorized Ammunition	Inspection Observations
Current A	Burgoyne and Wood Road	Mid-1970s to present	M2 Machine Gun	.50 caliber plastic	2 fixed firing positions accommodating vehicle-mounted guns , numerous .50 caliber plastic projectiles downrange, natural embankment backstop
Current B	Burgoyne and Wood Road	1991 to present	M16 Rifle and Pistols	5.56 mm ball and tracer, .45 caliber and 9 mm ball	55 firing positions, targets at 25 m, numerous plastic projectiles on berm backstop
Current C	Burgoyne Road	1986/1989 to present	M16 Rifle and Pistols	5.56 mm ball and tracer, all pistol calibers	Identical to Current B Range except incomplete berm backstop
Current D	Burgoyne Road	1986/1989 to present	M60 Machine Gun	7.62 mm ball and tracer	8 firing positions, targets at 10 m, natural embankment backstop
Current E	Burgoyne Road	1986/1989 to present	Pistols	All pistol calibers	15 firing positions, pop-up targets, partial natural embankment backstop
Current G	Pocasset-Forestdale Road	Late 1980s to present	M16 Rifle, M249 SAW, Submachine Gun, Pistols, Shotgun	5.56 rifle and SAW ball and tracer, 7.62 mm ball and tracer, .45 caliber, 9mm, all pistol calibers	27 firing positions, targets at 25 m, numerous plastic rounds on berm backstop, metallic projectiles on downrange side of berm
Current H	Pocasset-Forestdale Road	Late 1980s to present	Identical to Current G Range	Identical to Current G Range	Identical to Current G Range

Range Name	Location	Period of Use	Training Activity	Authorized Ammunition	Inspection Observations
Current I	Pocasset-Forestdale Road	Late 1980s to 1991	Identical to Current G Range	5.56 mm ball and tracer, .45 caliber, 9 mm, All pistol calibers, shotgun	Identical to Current G Range
		1960 to Late 1980s (Old F Range)	Tank-mounted machine gun and rifle	.30 caliber, 5.56 and 7.62 mm ball	10 firing positions, moving target on rails, metallic projectiles on downrange side of berm
IBC	Gibbs Road		Rifle, Submachine Gun, Smoke Pyro	.22, 5.56 and 7.62 mm ball and blank, 40 mm smoke, 22 mm sub-caliber	5 maneuver lanes
Current J	Pocasset-Forestdale Road	Late 1980s to present	M16 Rifle and SAW, Submachine gun, Pistols, Shotgun	5.56 mm rifle and SAW, Submachine gun, .45 caliber, 9 mm, shotgun, all pistol calibers	8 firing positions, targets at 25 m, metallic .30, .40, .50 caliber, and 5.56 mm projectiles on downrange side of berm
		(Old Air Force A Range)	Pistols	.38 caliber	
Current K	Pocasset-Forestdale Road	Late 1980s to present	Identical to Current J	Identical to Current J	18 firing positions, targets at 25 m
		(Old Air Force B Range)	Pistols	.38 caliber	Approximately 30 firing positions
KD Small Arms Range	Pocasset-Forestdale Road	Mid-1980s to present	M16 Rifle and SAW, 7.62 mm Machine Gun and Rifle, Pistols, Shotgun	5.56 and 7.62 mm ball and tracer, .45 caliber, 9mm, all Pistol calibers, shotgun	35 firing positions on western side, targets at 25 m, 20 firing positions on eastern side with firing points positioned at 100 m, and 100, 200, 300, 400, and 500 ft from targets (mechanical)

Range Name	Location	Period of Use	Training Activity	Authorized Ammunition	Inspection Observations
		Mid-1970s (Old Aerial Gunnery Range)	CRT-1 and CRT-2		
Current N	Greenway Road	1986/1989 to present	Rifle, Pistols, Shotgun	5.56 mm ball and tracer, all Pistol calibers, Shotgun	55 firing positions, targets at 25 m, numerous plastic projectiles on backstop berm
Current O	Greenway Road	1986/1989 to present	Shotgun Familiarization, Pistols	Shotgun, all Pistol calibers	Bermed on four sides, firing points at 3, 5, 7, 10, 15, 25, and 50 yds from targets
Current P	Greenway Road	1986/1989 to present	Rifle, Pistol, Shotgun	5.56 mm ball and tracer, all pistol calibers, Shotgun	26 firing positions, targets at 25 m
S East	Gibbs Road	1986/1989 to present	Rifle and Machine gun	5.56 and 7.62 mm ball and tracer	Mounded firing point with 5 firing positions, targets at 100 through 800 m, no berm backstop
S West	Gibbs Road	1986/1989 to present	Rifle and Machine gun	5.56 mm and 7.62 mm ball and tracer	Mounded firing point with 5 firing positions, targets at 100 through 800 m, no berm backstop
Current T	Gibbs Road	2006-present	Rifle	5.56 mm	15 lane 25 bermed range with 1 STAPP installed, 6 dismounted firing positions and 4 mounted firing positions, targets up to 300 m downrange, numerous plastic projectiles, no berm backstop
		1990/1991 to 2006	Machine gun	.50 caliber	
		1967 to 1990/1991 (Old P Range)	Night defense/ squad and platoon attack course	Blank only	
Former B	Monument Beach Road	1967 to early 1980s	1000-inch rifle	0.30 caliber, 5.56 and 7.62 mm	25 to 27 firing positions, combination hillside and constructed berm backstop, metallic projectiles and pockmarked boulders

Range Name	Location	Period of Use	Training Activity	Authorized Ammunition	Inspection Observations
		1955 to 1967	Pistol	0.38 and 0.45 caliber	Targets at 15 and 25 yds from firing point
		1935/1941 to 1955 (Former Machine Gun A Range)	1,000-inch machine gun and pistol	.30, .38, .45, and .50 caliber ball	
Former C	Frank Perkins Road	1950s to 1986/1989	1,000-inch Machine Gun	.30 caliber and 5.56 and 7.62 mm	55 firing positions, natural hillside backstop, numerous metallic projectile fragments and pockmarked boulders at top of slope
		1935/1941 to 1950s (Former Machine Gun B Range)	Machine Gun	.30 and .50 caliber ball and tracer	

Range Name	Location	Period of Use	Training Activity	Authorized Ammunition	Inspection Observations
Former D	Frank Perkins Road	Late 1980s to present	Pistol	All pistol calibers	Berm backstop in former parking area
		Early 1960s to late 1980s	Rifle	.30 caliber and 7.62 mm ball	44 firing positions
		1950s to early 1960s	1,000-inch machine gun	.50 caliber ball	20 firing positions
		1935/1941 to 1950s	Anti-Aircraft Miniature	.22 caliber ball	No constructed berm, numerous metallic projectiles found on surface downrange
GA/GB	Dolan Road	1935/1941 to 1950s	Rifle	.30 caliber ball	GA: 150 firing positions at 100 and 200 yds from target area, soil berm remnant with metallic projectiles. GB: 70 firing positions, targets at 100, 200, and 300 yds from target area
Former R	Gibbs Road	1967 to early 1980s	Squad battle assault course	.30 caliber and 7.62 mm	No discernable range remnants
Skeet 1	Howe and Turpentine Road (BA-1)	1940s	Shot gun skeet		Single fragment of clay skeet, no discernable range remnants
Succonsette Pond	Impact Area	Unknown	Machine gun	.50 caliber	No evidence of firing point, targets, or backstop found
M-1	Greenway and Pocassett-Forestdale Road	1940s	Submachine gun	.45 caliber	Remnants of 5 target frames, no evidence of firing point, no berm backstop
M-2	Original Greenway Road	1940s	Submachine gun	.45 caliber	Remnants of a former backstop berm and 30 target frames, numerous metallic projectiles on berm

2.3 General Lead Chemistry

Lead is the heaviest stable element on Earth and as a Group (IV) element has four valence electrons, but unlike carbon, germanium, and other members of this group, is mostly present in the oxidation state of (+2) in the environment. In surface waters, soils, and in the earth's crust, across the natural range of Eh (redox potential) and pH (measure of the acidity of a solution in terms of activity of hydrogen (H^+)) lead (II) is usually found as a hydrated Pb^{2+} cation, or as dissolved or solid compounds where it bonds directly to other inorganic species. There are also organo-lead compounds: where lead is most commonly in the tetravalent (lead (IV)) state. Organo-lead compounds have been synthesized for a variety of applications. Most notably, tetraethyl lead and tetramethyl lead compounds were used during the middle of the 20th century as antiknock additives in gasoline's and other fuels but their use has been discontinued. Tetravalent lead compounds are not very stable, and are found in very low abundance today, even in soils that were substantially impacted by gasoline containing lead-additive and other types of fossil fuel combustion (Shotyk *et al.* 2002).

Lead (II) or Pb^{2+} is a relatively immobile element in the terrestrial environment. In addition to forming a range of stable mineral phases in both oxygen-rich and oxygen-poor environments (Nriagu 1974, DeVolder *et al.* 2003, Jackson *et al.* 2005), lead (II) can form strong inner-sphere (lead binds to surface directly with no intervening water molecule) and outer-sphere (lead binding to surface within hydration shell) adsorption complexes on surfaces of quartz, humus, iron oxides, aluminum oxides, manganese oxides, and virtually any mineral with oxygen or sulfur atoms at the surface (Bargar *et al.* 1997a, 1997b, 1998, 1999, Xia *et al.* 1997, Sauvé *et al.* 2000a,). Dissolved lead phases can be some combination of Pb^{2+} and its hydrolysis species, lead bound to dissolved organic matter (DOM), and lead complexes with inorganic ligands such as chloride and sulfate anions. Eh and pH are two of the more important variables governing mobility, speciation, and potential toxicity of lead in the environment. Presence of ligands or organic matter in solution that can form complexes with lead can inhibit the precipitation of lead minerals and adsorption, thus allowing more lead to remain more soluble (Sauvé *et al.* 1998, Lang and Kaupenjohann 2003). Redox potential can be considered an indirect assessment of the amount of oxygen present. The presence of oxygen in soil and groundwater creates an oxidizing (aerobic) environment, whereas an absence of oxygen results in a reducing (anaerobic) environment. The concentration of dissolved lead species in soil solution, surface water, or groundwater is thus controlled by some combination of 1) lead mineral solubility equilibria, 2) adsorption reactions of dissolved lead phases on inorganic surfaces (e.g. crystalline or amorphous oxides of aluminum, iron, silica, manganese, clay minerals etc.), and 3) adsorption reactions of dissolved lead phases on soil organic matter (e.g. humus).

Anthropogenic activities have dispersed lead into the environment, causing the lead content of soils, vegetation, surface water, and many organisms to be elevated relative to natural (pre-

industrial) levels (Nriagu and Pacyna 1988, Nriagu 1990, Candelone *et al.* 1995). Ancient and recent atmospheric pollution associated with smelting, iron and steel foundries, the combustion of fossil fuels in automobiles, trucks, airplanes, and ships, the manufacturing of cement, and other industrial processes has dispersed lead to even the most remote environments on earth (Erel and Patterson 1994, Candelone *et al.* 1995, Kaste *et al.* 2003, Yanai *et al.* 2004, Van de Velde *et al.* 2005, Meena *et al.* 2006, Wang and Guo 2006). Furthermore, point sources of lead to the environment, such as building paint with lead additive, shooting ranges, pesticide applications, and mine tailings can result in lead loadings to the environment several orders of magnitude higher than normal (Adgate *et al.* 1998, DeVolder *et al.* 2003, Vantelon *et al.* 2005). Unfortunately, lead can be toxic to many soil fauna, vascular plants, small mammals, birds, and even humans as mentioned in Section 1 (Needleman *et al.* 1990, Nriagu *et al.* 1996, Bongers *et al.* 2004). Laboratory evidence suggests concentrations as low as 200 mg/kg can disrupt organic matter decomposition and associated nitrogen and phosphorous mineralization processes necessary for effective recycling of essential nutrients in ecosystems (Rühling and Tyler 1973, Ekenler and Tabatabai 2002).

2.3.1 Lead Immobilization in the Terrestrial Environment: Lead Minerals

Given Pb^{2+} concentrations > 200 µg/L, a number of stable and sparingly-soluble minerals may precipitate (Figure 3). Neutral and alkaline soils may have solutions supersaturated with respect to cerussite ($PbCO_3$), hydrocerussite ($Pb_3(CO_3)_2(OH)_2$), lead oxide ($Pb(OH)_2$), lead phosphate ($Pb_3(PO_4)_2$), hydroxylpyromorphite ($Pb_5(PO_4)_3(OH)$), and hydroxopyromorphite ($Pb_4O(PO_4)_2$) (Badawy *et al.* 2002). Lead phosphate minerals in particular, are so sparingly soluble, thermodynamic data predicts these phases will control dissolved lead in soil solution under the Eh and pH conditions commonly found in natural systems (Figure 3, Nriagu 1974, Ma *et al.* 1993, Ruby *et al.* 1994). In other environments, poorly soluble lead carbonates such as ($PbCO_3$) or ($Pb_3(CO_3)_2(OH)_2$) (Rimstidt and Craig 2000), and lead sulfates such as anglesite ($PbSO_4$) also may form. Under reducing conditions in which sulfate is reduced to sulfide, lead may be sequestered in galena (PbS) a lead sulfide, which has a solubility in natural waters too low to be measured by current technology. Consequently, under the normal range of soil pH and redox conditions, aqueous lead concentrations should generally be limited to low values through precipitation reactions.

Despite the potential formation of poorly soluble lead minerals (e.g. chloropyromorphite ($Pb_5(PO_4)_3Cl$)) in soil, very few studies have directly shown these lead minerals actually buffer lead concentrations in natural aqueous environments. For example, Kaste *et al.* (2006) used microfocused synchrotron-based X-ray diffraction (µSXRF) to analyze lead-enriched soil grains sampled from the northeastern US. They reported no evidence of any crystalline lead phases in their samples. Manceau *et al.* (1996) also used synchrotron-based x-ray studies on soils collected from contaminated sites in France, and concluded lead was bound with organic matter

and silicate minerals. Efforts to speciate soil lead using selective chemical extractions typically conclude lead is bound to organic matter, and secondary iron, aluminum, and manganese phases (Johnson and Petras 1998, Erel *et al.* 2001, Emmanuel and Erel 2002, Kaste *et al.* 2005) rather than to discrete lead minerals. At Camp Edwards, the low organic matter levels indicate the primary binding mechanism is the result of lead precipitate formation with aluminum, iron, and manganese. As a result, considerable care is necessary when evaluating environmental fate of metals based on phase diagrams alone. In particular, appropriate phase diagrams need to include a complete and accurate description of composition and other associated mineral phases. Nonetheless, several researchers have found phase diagrams to be an effective means of evaluating lead mobility (Hermann and Neumann-Mahikau 1985, Reddy *et al.* 1995, Vasquez *et al.* 2006).

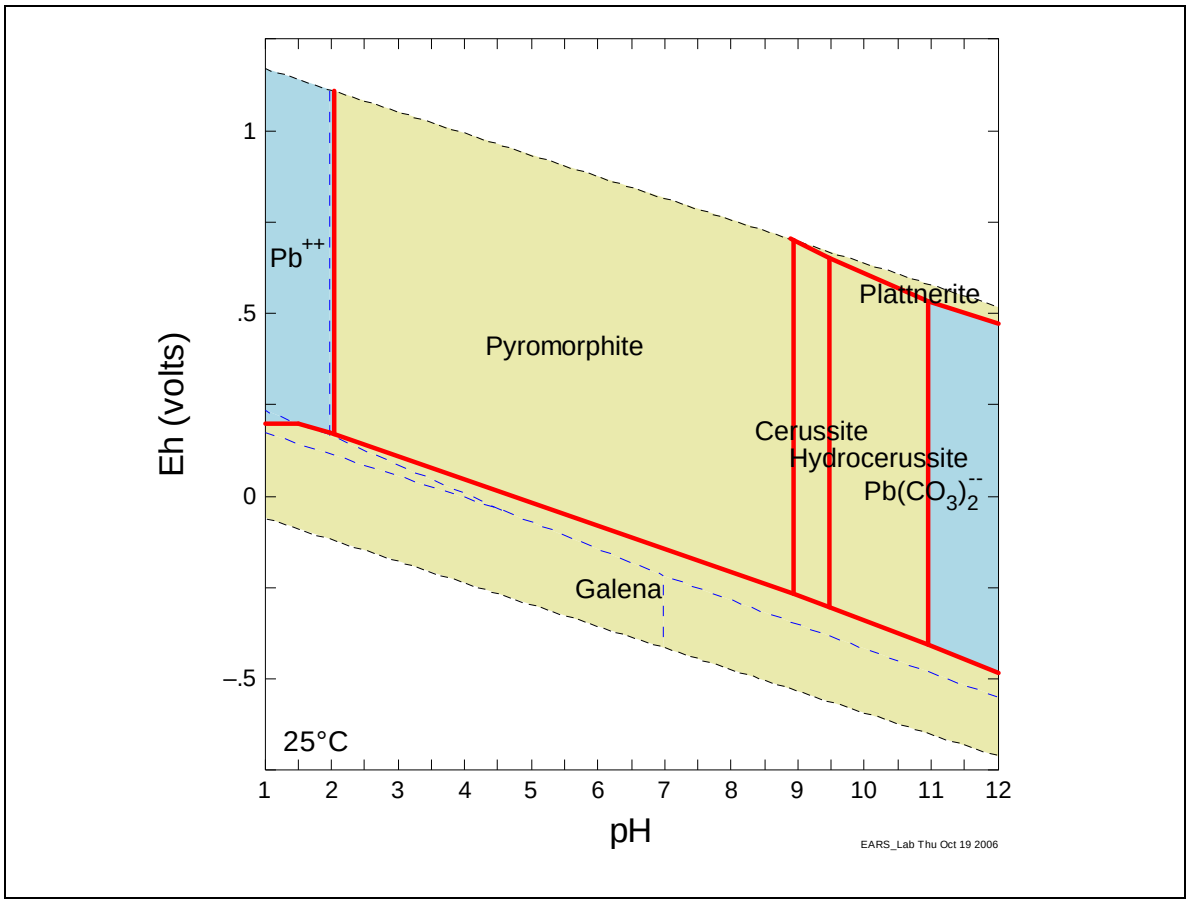

Figure 4. The formation of stable lead minerals as a function of Eh and pH given [Pb] = 10^{-6} M, [SO_4] = 10^{-3} M, [HCO_3^-] = 10^{-2} M, [Cl^-] = 10^{-6} M, [HPO_4^{-2}] = 10^{-6} M. More concentrated lead solutions would result in slightly larger stability fields for solids.

Recent studies have begun to shed light on the potential importance of biomineralization in regulating lead in the environment (Templeton *et al.* 2003). Jackson *et al.* (2005) used μSXRF to detail the distribution of lead and copper in the nematode *Caenorhabditis elegans*. They found that while copper was evenly distributed throughout the bodies of exposed *Caenorhabditis elegans*, lead was concentrated in the anterior pharynx region. Microfocused X-ray diffraction indicated the highly concentrated lead regions in the pharynx were actually the crystalline lead minerals pyromorphite. The authors concluded *Caenorhabditis elegans* precipitated pyromorphite in the pharynx as a defense mechanism to prevent spreading the toxic metal to the rest of the organism's body. Jackson *et al.* (2005) further suggest that because of the high turnover rate of nematodes, biomineralization could play an important role in the speciation of lead in certain soils.

A number of factors can inhibit the precipitation of lead minerals from solution. The pH and Eh of the solution are two direct controls on mineralization (Figure 4). However, certain chelating agents such as DOM may increase lead mobility (Jordan *et al.* 1997). Thus, DOM, and, in some cases, the availability of reactive surfaces can keep the Pb^{2+} below the saturation threshold. Jackson *et al.* (2005) suggested DOM could significantly inhibit pyromorphite precipitation by lowering dissolved lead activities. Alternatively, in certain natural environments, organic matter turnover may immobilize phosphate and thereby maintain a geochemical environment undersaturated with respect to pyromorphite. While dissolved lead complexes may buffer the activity of Pb^{2+} in solution and prevent precipitation of mineral phases, reactive surfaces on soil minerals can also sequester Pb^{2+} and can have a similar effect of inhibiting mineral formation (Figure 5). This may be the case for most environments at the earth's surface.

2.3.2 Lead Immobilization in the Terrestrial Environment: Lead Adsorption to Surfaces

Many studies have directly demonstrated Pb^{2+} can form strong complexes with the surfaces of soil particles, including pure quartz (Schindler *et al.* 1976, Chen *et al.* 2006), iron phases (Bargar *et al.* 1997b, Ostergren *et al.* 2000a, 2000b, Sauvé *et al.* 2000a, Trivedi *et al.* 2003), manganese phases (Drits *et al.* 2002, Lanson *et al.* 2002, Manceau et al. 2002), aluminum phases (Bargar *et al.* 1997a, 1997b), and organic matter (Xia *et al.* 1997, Sauvé *et al.* 1998, 2000a, Strawn and Sparks 2000). The adsorption of lead to mineral and organic matter surfaces can be explained in terms of surface complex formation involving deprotonated hydroxide–[OH] groups and is thus strongly dependent on pH (Figure 6).

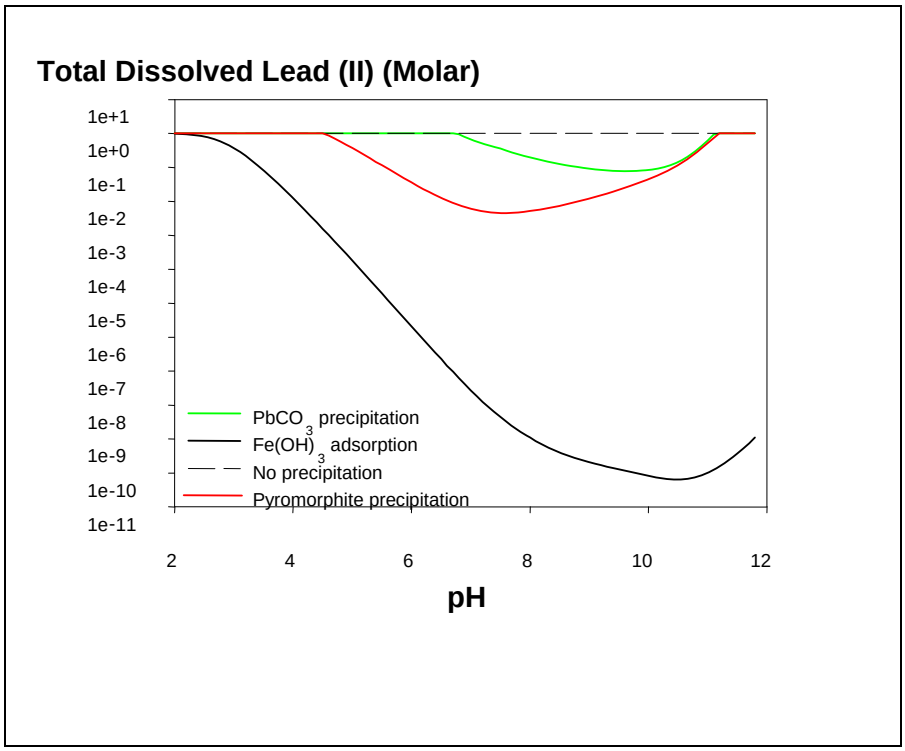

Figure 5. Buffering mechanisms of lead in aqueous environments, given: [Pb] = 10^{-6} M, [SO_4] = 10^{-3} M, [HCO_3^-] = 10^{-3} M, [Cl^-] = 10^{-4} M, [HPO_4^{-2}] = 10^{-6} M. Adsorption conditions: 1.4 g/cm3 bulk density, 2% Fe(OH)3 by weight in soil. The hatched area delineates the range of typical soil conditions. Thus, adsorption in most cases appears to effectively moderate lead levels to lower concentrations than the precipitation processes.

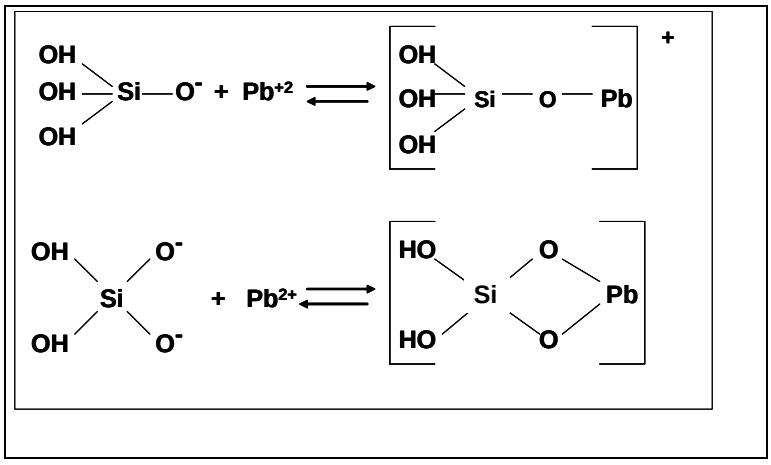

Figure 6. Conceptual framework for the adsorption of Pb^{2+} to surface silanol groups on quartz. Adsorption can be both monodentate (upper) and bidentate (lower). Similar reactions could be given for acidic surface groups on organic matter, iron, aluminum, or manganese. (Modified from Schindler et al. 1976.)

Lead is often more strongly retained by surfaces than other divalent trace metals such as cadmium (Cd^{2+}), copper (Cu^{2+}), cobalt (Co^{2+}), manganese (Mn^{2+}), nickel (Ni^{2+}), and zinc (Zn^{2+}). This is attributed to lead's larger hydrolysis constant (log K = -7.71) compared to the previously mentioned metals (log K = -8 to –11) (Abd-Elfattah and Wada 1981, Stumm and Morgan 1996).

Lead typically will form inner-sphere complexes with mineral surfaces and organic matter, which is a stronger and less reversible adsorption mechanism than general electrostatic adsorption by ion exchange. Even though lead tends to hydrolyze significantly only above pH 7, experimental data often show a sharp adsorption edge (i.e. the pH where lead switches rapidly from Pb^{2+} in solution to a surface bound species) near pH 4 (McKenzie 1980, Dzombak and Morel 1990, Glover *et al.* 2002). Strong binding of lead to soil even in relatively acidic pH ranges is a result of its high electro negativity, which causes it to form strong covalent bonds with oxygen atoms on mineral surfaces and organic matter functional groups (McBride 1994). Partition coefficients (K_d) are generally >100 milliliter per gram [mL/g]) for lead in the normal soil pH range (see Section 3.10), where

1} $(K_d = [Mass]_{adsorbed}/[Mass]_{solution})$

where

Mass $_{adsorbed}$ = mass of solute on solid phase per unit mass of solid phase milligram per gram (mg/g) at equilibrium.

Mass $_{solution}$ = mass of solute in solution per unit volume milligram per milliliter (mg/ml) of the liquid phase at equilibrium.

Sauvé *et al.* (2000b) demonstrated the quantity of free Pb^{2+} in equilibrium with leaf compost at pH 4 was lower than the amount adsorbed by a factor of approximately 100 (Log K_d = 2 ml/g).

While the exact K_d value is a function of pH, organic matter content, substrate type, total metal burden, and concentrations of competing ligands, these studies typically show lead has very strong solid-phase partitioning. Partitioning coefficients determined by differential pulse anodic stripping voltammetry (DPASV) generally range from 10^3 to 10^6 in soils in the typical pH range (Suavé *et al.* 2000b). Aualittia and Pickering (1987) used thin film anodic stripping voltammetry to compare the relative affinity of lead for different inorganic particulates and reported manganese (IV) oxides completely adsorbed the lead, regardless of pH in the range of 3 to 9, and had the highest affinity for lead in their study. The adsorption of lead to pedogenic iron oxides, aluminum hydroxides, clay minerals, and iron ores was reported to be pH dependent. Sauvé *et al.* (1998) used DPASV to study the effects of organic matter and pH on lead adsorption to an orchard soil and demonstrated lead complexation to DOM increased lead

solubility, and 30 to 50% of the dissolved lead was bound to DOM at pH 3 to 4, while >80% of the dissolved lead was bound to DOM at neutral pH. They concluded in most soils lead in solution would not be Pb^{2+} but bound to DOM. Sauvé *et al* (2000a) compared the relative affinity of Pb^{2+} for synthetic ferrihydrite, leaf compost, and secondary oxide minerals collected from soils. They reported the inorganic mineral phases were more efficient at lowering the amount of Pb^{2+} available in solution than the leaf compost. Glover *et al.* (2002) used DPSAV to study the effects of time and organic acids on lead adsorption to goethite and found lead adsorption to goethite was very rapid, and remained unchanged after a period of about 4 hours. Lead desorption was found to be much slower however, and adsorption was not reversible on a timescale of 8 hours.

In the case of adsorption phenomena, total metal loading also controls the partitioning of Pb^{2+} to the solid phase: high lead loadings will result in a lower fraction partitioned to the solid phase. Sauvé *et al.* (1997, 1998) demonstrated only a fraction of the total lead in solution was actually Pb^{2+} in soils treated with leaf compost. The fraction of Pb^{2+} to total dissolved lead ranged from <1 to 60%, depending on pH and the availability of lead-binding ligands. In acidic soils, aluminum species can compete for sites on natural organic matter and inhibit lead binding to surfaces (Gustafsson *et al*. 2003). Interestingly, for a given pH, the total loading of the metal does not appear to affect the type or geometry of the adsorption complex. Trivedi *et al.* (2003) found that a mixture of monodentate and bidentate adsorption complexes formed on the ferrihydrite surface, and that their relative proportions were not related to loading.

The presence of chloride, sulfate, ligands, etc. and other complexing agents (DOM) in solutions can have a range of effects on the type and amount of adsorption of lead to surfaces. Ligands can increase or decrease the total amount of lead adsorption, change the geometry of the interaction, and affect the rate of the reaction (Strawn and Sparks 2000). The precise effect carbonate concentrations have on lead adsorption to mineral surfaces is a function of pH. At neutral to high pH, dissolved lead-carbonate complexes can inhibit adsorption, but at pH < 6.5 lead adsorption increases (Ostergren *et al.* 2000b). Ostergren *et al.* (2000b) obtained spectroscopic evidence that carbonate groups bond to lead as monodentate ligands. Increased uptake of lead onto the solid phase may result if surfaces have a higher affinity for these lead-carbonate ternary complexes that are stable in slightly acidic waters. Other evidence exists showing low-molecular weight organic acids can also form ternary complexes with lead and enhance surface adsorption (Schroth and Sposito 1998, Lenhart *et al*. 2001). The presence of sulfate in solution will enhance uptake of lead onto goethite across the pH range of 5 to 7, and will change the geometry of the lead complexes. While Pb^{2+} either will form inner-sphere complexes with corners or edges of Fe (O, OH) 6 octahedra, the relative fraction of corner sharing complexes increases in the presence of sulfate (Ostergren et al. 2000a).

2.3.3 Lead Fate and Transport in Environments with Relatively Low Levels of Lead (Concentrations < 0.1% or 1,000 mg/kg)

Surface soils across the US have higher lead concentrations relative to levels expected from solely natural geogenic inputs (Friedland *et al.* 1984, Francek 1992, Erel and Patterson 1994, Marsh and Siccama 1997, Murray *et al.* 2004, Yanai *et al.* 2004). While some of this lead is attributed to paint, salvage yards, and the use of lead arsenate as a pesticide in localized areas (Francek 1997), lead contamination of surface soils is essentially ubiquitous because of atmospheric pollution associated with the metal and cement production industries and the combustion of fossil fuels. Surface soils in Michigan, for example, typically range from eight to several hundred-mg/kg lead (Francek 1992, Murray *et al.* 2004). Soils collected and analyzed beneath 50 centimeters (cm) in Michigan, however, range only from 4 to 60 mg/kg lead (Murray *et al.* 2004). In remote surface soils from the Sierra Nevada Mountains, litter and upper soil horizons are 20 to 40 mg/kg lead approximately 75% of which is attributed to atmospheric deposition during the 20th century (Erel and Patterson 1994). Repeated sampling of the forest floor (O horizon) in the northeastern US demonstrates the organic layer has retained much of the lead load deposited during the 20th century at 1 to 3 grams per square meters (g/m^2), depending on elevation and proximity to urban areas (Miller and Friedland 1994, Johnson *et al.* 1995). Forest floors sampled during the 1980s, 1990s, and early 2000 had between 0.7 and 2 g/m^2 (Friedland *et al.* 1992, Miller and Friedland 1994, Johnson *et al.* 1995, Kaste *et al.* 2003, Yanai *et al.* 2004, Evans *et al.* 2005). The direct uptake of anthropogenically-derived lead by vegetation in boreal forests appears to be low (Klaminder *et al.* 2005), although one study suggested the presence of pine seedlings significantly reduced the amount of bioavailable lead (Turpeinen *et al.* 2000). An example of low uptake in boreal forests is provided by data from the Hubbard Brook Experimental Forest in New Hampshire where the pool of lead in above and below-ground biomass is approximately 0.13 g/m^2 (Johnson *et al.* 1995).

In the majority of cases of lead pollution from atmospheric deposition, concentrations in soil are typically in trace amounts. There has been a considerable amount of effort directed to assess the speciation, transport, and fate of atmospherically delivered lead in the terrestrial environment. Soils are effective at immobilizing lead from the atmosphere, and minimizing surface and groundwater contamination, and the residence time in soils is typically estimated to be on the order of >100 years (Wang *et al.* 1995, Wang and Benoit 1996, 1997, Kaste *et al.* 2003, Klaminder *et al.* 2006a, 2006b,). Overall, there is very little evidence lead mobility and solubility in these cases is controlled directly by the precipitation of lead minerals. Sequestration of relatively small amounts of lead is attributed to adsorption processes, although different soil types appear to sequester lead via different mechanisms. Teutsch *et al.* (2001) found most of the anthropogenic lead in soils from their study in Israel was associated with carbonates and iron oxides. Emmanuel and Erel (2002) reported organic matter was largely responsible for lead retention in soils from the Czech forest. Within O soil horizons, extractions targeting organic

matter and reducible oxides can liberate a significant quantity of lead (Johnson and Petras 1998, Ho and Evans 2000, Kaste *et al.* 2005). Manceau *et al.* (1996) used X-ray absorption spectroscopy on soil samples collected from areas contaminated by alkyl lead, and concluded lead in these samples lead was bound to salicylate and catechol-like functional groups. Other data suggests lead may bind directly to iron surfaces in addition to organic matter functional groups in organic-rich samples (Tessier *et al.* 1996, Kaste *et al.* 2006).

2.3.4 Lead Fate and Transport in Environments with Relatively High Levels of Lead (Concentrations > 0.1% or 1,000 mg/kg)

In addition to the ubiquitous lead residue resulting from atmospheric deposition, which has elevated soil levels an order of magnitude or two above natural (pre-industrial) levels, a number of anthropogenic activities have resulted in extremely high loadings to soils on a more localized scale. Soil contamination by leaded paint, projectiles, mine tailings, and short-range transport of smelter emissions has resulted in soils containing thousands of parts per million to percent level lead (Morin *et al.* 1999, DeVolder *et al.* 2003, Vantelon *et al.* 2005, Clark *et al.* 2006). In these cases, the dissolved concentration in soil pore-water is controlled by a combination of lead mineral precipitation and surface adsorption processes (Morin *et al.* 1999, 2001, Cao *et al.* 2003a, 2003b, Vantelon *et al.* 2005). Direct uptake of lead by vegetation, soil organisms, birds, and mammals has been observed at many of these sites, in addition to elevated levels in nearby surface waters (Clark *et al.* 2006). Cao *et al.* (2003b) analyzed soils, waters, and vegetation at several firing ranges in Florida. They reported lead concentrations in grasses up to 800 mg/kg, and surface water concentrations up to 289 µg/L at these sites. Several other studies have documented significant lead uptake by vegetation and earthworms from soils at shooting ranges (Darling and Thomas 2005, Levonmaki *et al.* 2006).

Soils with high lead concentrations may exhibit different geochemical behavior. Some of the difference in geochemical behavior is attributed to differences in adsorption in highly contaminated sites. Adsorption of lead to minerals controls the fate of lead in sites with low lead concentrations, but is nonlinear and limited by mineral surface area. In some contaminated environments, the lead concentration may be sufficiently high that adsorption is less effective at moderating lead levels. This effect on adsorption is most pronounced when the mineral grains are saturated and have no other available surface area for lead retention; however, partial saturation may decrease the effective partition coefficient for lead retention sufficiently to affect dissolved lead levels. In such cases, the lead concentration may be elevated somewhat from background levels, and other lead-bearing phases (such as the formation of discrete lead minerals) may form. Two such minerals, cerussite or hydrocerussite are frequently found in highly contaminated soils because soils often contain appreciable bicarbonate (Lin 1996, Cao *et al.* 2003a, 2003b, Vantelon *et al.* 2005). These minerals do not commonly form in less contaminated environments because lead concentrations are buffered to lower levels by

adsorption, consequently, the solutions remain undersaturated with respect to each mineral. These minerals, although still not highly soluble, are considerably more soluble than adsorption complexes. More importantly, the precipitation of these minerals may not proceed until the solution is considerably supersaturated, allowing dissolved lead to persist in concentrations in excess of predicted solubility. As a result, lead concentrations may not agree (and may exceed) the concentrations predicted based on thermodynamic properties such as solubility (Badawy *et al.* 2002). Once the mineral precipitates form, however, their relative insolubility may decrease dissolved lead levels considerably. .Munitions containing lead are high concentration "nuggets" in soil that will corrode in place; resulting in localized regions of elevated Pb^{2+} levels. These elevated dissolved lead levels will, however, be relatively short-lived in that the mineral precipitates, once formed, bring lead into essentially insoluble phases; thus, corrosion processes will not likely result in the mobilization of lead from the range. Consequently, even in highly contaminated soils, aqueous lead levels may be elevated in or near soil embankments used as bullet stops, but usually remain at or near background levels deeper in the soil profile (Bricka 1996a, 1996b, Bricka *et al.* 1998, Astrup *et al.* 1999).

The mineralogy of lead in weathering crusts around the projectiles, which will control dissolved Pb^{2+}, is typically a mixture of litharge, hydrocerussite, cerussite, and massicot (Rimstidt and Craig 2000, Cao *et al.* 2003b, Vantelon *et al.* 2005). Vantelon *et al.* (2005) used µSXRF and x-ray diffraction to study the sequence of mineralogy surrounding corroding projectiles, from the core of the projectile to the surrounding soil. They concluded that as lead oxidized from Pb^0 to Pb^{2+} during corrosion, the weathering sequence was from litharge to hydrocerussite to cerussite. In firing range soils with adequate phosphorous concentrations (>3,000 mg/kg), pyromorphite has been observed, which would theoretically maintain the lowest solution Pb^{2+} concentrations (Figure 7).

Soils developed on mine tailings and on lead ore-deposits can also provide a useful setting for understanding retention mechanisms that develop during pedogenesis (Merrington and Alloway 1992) . It appears both mineral precipitation and adsorption reactions can control lead solubility (Morin *et al.* 1999, 2001). Ostergren *et al.* (1999) examined the speciation of lead in chemically distinct mine tailings from Leadville, Colorado. In mine tailings dominated by carbonates having near-neutral pH, adsorbed lead (inner-sphere) on iron (hydr) oxides accounted for approximately 50% of the total lead in the solid phase, with galena and lead carbonates making up most of the remainder. However, on more acidic tailings, lead phases were dominated by lead-bearing jarosites ($KFe_xPb_x(SO_4)_2(OH)_6$). Adsorbed phases appear to be favored by high pH conditions, but at low pH, discrete mineralized lead-bearing phases control the dissolved Pb^{2+} (Morin et al. 1999). In other soils developed on a mineralized bedrock parent material, lead phases can be dominated by plumbogummite ($PbAl_3(PO_4)_2(OH)_5 \cdot (H_2O)$), pyromorphite, and adsorbed lead (Morin et al. 2001).

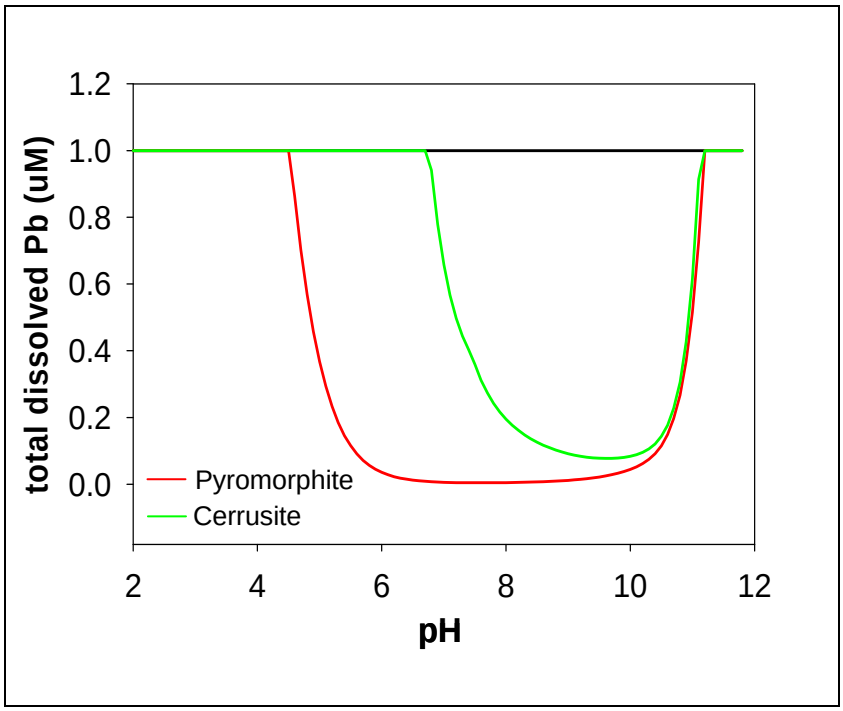

Figure 7. Impact of mineral precipitation on total dissolved lead levels. Conditions are based on the average soil chemical conditions at Camp Edwards: 1 µM total P, 0.2 µM Cl, 1 µM carbonate and sulfate. Pyromorphite (red) maintains the lower equilibrium dissolved lead concentrations than cerussite (green). The black line represents zero mineral precipitation. Calculated using Visual Minteq 2.42 using the USEPA Minteq thermodynamic database.

In summary, lead migration is minimal in most environments due to adsorption or the formation of sparingly soluble mineral phases (Nriagu 1974, DeVolder *et al.* 2003, Jackson *et al.* 2005). Attenuation of lead in soil at SARs has been confirmed (Bricka 1996a, 1996b, Bricka *et al.* 1998, Scheetz 2004). Therefore, lead is usually immobile and not bioavailable even when, in contrast to Camp Edwards, the organic matter content of the soil is high (see Sections 2.4.1, 2.4.3, and 3.6 for additional discussion of organic matter and lead). Proper evaluation of the fate of lead in the environment requires an understanding of the dissolved and mineral bound chemical form. Accurate assessment of migration and bioavailability risks requires identification of the potential problematic areas in which lead concentrations may be elevated relative to other regions. Specialized environments exist in which contaminant lead may be more soluble and susceptible to transport. Although none of these are applicable to Camp Edwards, they are described below for completeness.

2.3.5 Transitional Redox Environments

Transitional redox environments are those of intermediate redox status that are undergoing dynamic change, becoming either more oxic or more anoxic. Under these conditions, adsorbed

lead is actively being released from iron oxides by reductive dissolution but sequestration processes, though still occurring, are not able to remove lead at the same rate and the result is a transient rise in aqueous lead levels. Continued reduction will remove lead from solution. Since reducing conditions may arise due to persistent soil saturation (e.g. flooding), lead levels may be elevated temporarily resulting from the onset of reducing conditions." Thus, iron-rich soil environments in which lead is adsorbed on mineral surfaces may experience elevated lead levels during periods of active geochemical reduction. Transitional redox conditions, however, are not typical of Camp Edwards.

The effect of transitional redox environments is easily observed in anaerobic incubation experiments in the presence of organic matter (Figure 8). Dissolved lead levels increase rapidly and reach a reasonably high level in response to the stimulation of iron (III) reduction (indicated by the release of soluble iron (II) into solution). This effect is kinetic—the system has available sorption sites and is precipitating practically insoluble minerals such as lead carbonate but those processes are unable to occur at a sufficient rate to remove all of the lead released during iron (III) reduction from solution. In fact, other active processes, such as sulfate reduction (which forms sulfide) may result in lead sequestration because dissolved lead may form the essentially insoluble (galena) PbS.

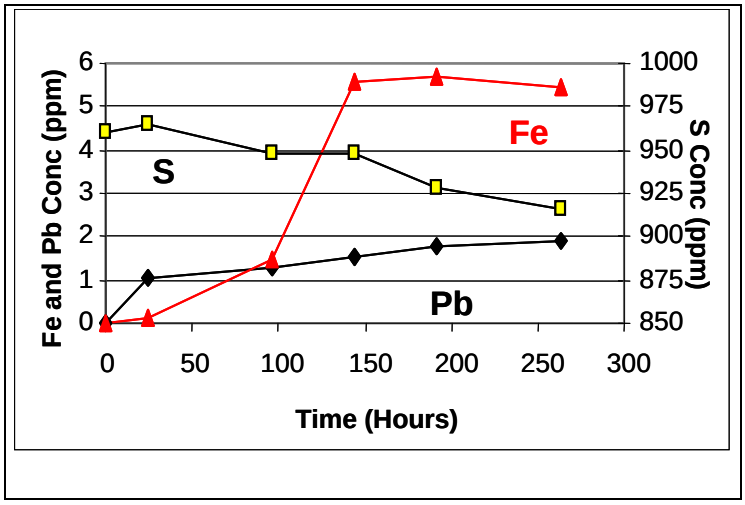

Figure 8. Anaerobic incubations of lead-contaminated soils from the Coeur d'Alene River region of Idaho. Total lead: about 4,000 mg/kg. *Data from Quicksall et al. (2005).*

Iron (III) reducing conditions are usually associated with soil flooding and/or redox processes below the water table. In the environment where these processes occur, pore-water lead levels can increase considerably due to active reduction during spring runoff. In fact, the near surface pore-water concentrations of lead are generally low (a few hundredths of milligram per liter

[mg/L]) due to scavenging by iron oxides and organic matter, but increase to nearly 0.250 mg/L in response to winter flooding events (Quicksall *et al.* 2005).

Emplacement of firing ranges on these unstable environments is generally undesirable to prevent lead-contaminated soils and materials encountering groundwater systems. Furthermore, monitoring groundwater concentration is prudent to evaluate the potential migration of lead towards groundwater in these systems.

2.3.6 Specific Solution Compositions

Metallic lead solubility is low and usually effectively limits transport from surface soils to the subsurface. However, the solubility of lead minerals (or adsorption complexes) may be considerably enhanced by the formation of solution complexes such as DOM (Weng *et al.* 2002, Lang and Kaupenjohann 2003). The effect of these complexes on lead solubility can be predicted using the parameterized lead-dissolved organic carbon (DOC) binding constants in the Visual MINTEQ thermodynamic database. The solubility of cerussite at pH 7 is about 124 µg/L (assuming a typical soil P_{CO2} of 0.0035 atmospheres. In the presence of 5,000 µg/L DOC; however, nearly all (approximately 98% of the Pb^{2+}) is bound to DOC and the cerussite solubility increases to about 5,175 µg/L. The increased solubility of lead in organic-rich systems has been observed in natural systems. In firing range soils, Cao *et al.* (2003a) observed measurable lead migration to depth in a near neutral soil and suggested this migration was a result of complexation with organic matter under those neutral to alkaline conditions.

Given the ubiquity of DOC in the environment, lead-DOC complexes may play an important role in increasing the solubility of lead minerals, although DOC levels at Camp Edwards are inferred to be minimal based on soil TOC measurements, see Sections 2.4.1, 2.4.3, and 3.6 (AMEC, 2004). Moreover, other ions, e.g., carbonate, sulfate) may also form a number of important solution complexes that need to be considered to assess the potential of lead migration in soils.

2.4 Summary of Camp Edwards Site Conditions

The following discussion is focused on the conditions in the context of Camp Edwards as a whole. Where site-specific information is available for the SAR this data is presented

2.4.1 Surface Soil Characteristics

Surface soils at Camp Edwards are coarse-grained and typically classified as sandy loams and loamy sands (Figure 9). These soils permit rapid recharge of percolating water and facilitate air exchange with the atmosphere. Measurements of 61 surface soil samples collected from within the Impact Area showed low average values for organic matter (1.8% or 18,000 mg/kg as compared to typical agricultural soils which range from 1 to 6%)) and pH (4.6) (Chendarian and

Stewart, 2004). The low pH values for the Impact Area samples may be related to collection adjacent to corroding unexploded ordnance. In a more recent study on tungsten mobility at Camp Edwards thirty-two samples from SAR impact berms were measured for soil pH with two field duplicates collected. The pH ranged from 6.2 to 7.4 with a median value of 6.5. There was no indication of pH difference according to the area under investigation or with the four background samples, areas not treated with Maectite™, where pH ranged from 6.4 to 7.0. At two locations, pH was measured with depth and no changes were evident. These pH measurements are consistent with the median pH of the soil pore-water (6.7). The difference in pH between the Impact Area and SARs may also be related to vegetation. The small arms berms have scarcely any vegetation and what is there consists of grasses. In contrast, the impact area is mostly pitch pine and scrub oak.

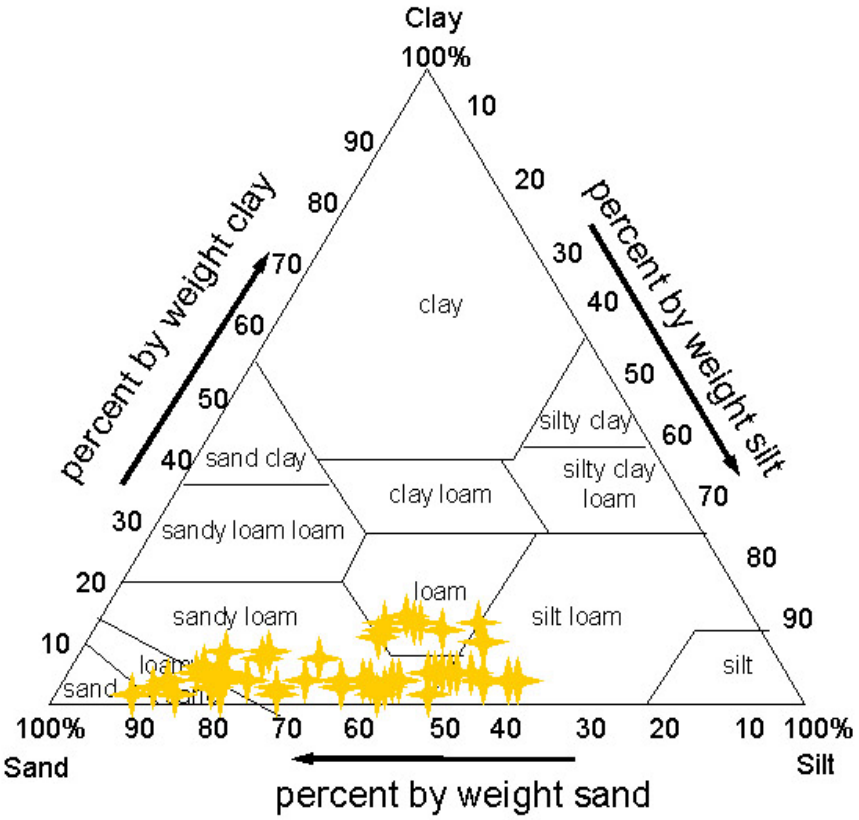

Figure 9. Classification of surface soil samples from Camp Edwards.

Total organic carbon (TOC) soil levels across Camp Edwards range from 31 to 247,000 mg/kg, with a mean of 11,050 mg/kg. A few soil horizons have a more developed organic layer present but in most locations, an organic rich surface soil is absent. The quantity of organic matter and the moisture content decrease significantly with depth. Clay-sized particles (traces in most samples) and cation exchange capacity (CEC) (8 to 10 millequivalents (meq)/100 g), factors

affecting sorption processes, are low in the surface soils and lower still in deeper soils. These soils have low concentrations of soluble salts (e.g. base cations such as calcium and magnesium as well as sodium and chloride) because these ions have been removed by leaching.

2.4.2 Hydrogeologic Setting

The geology of Western Cape Cod is comprised of glacial sediments deposited during the retreat of the Wisconsin stage of Holocene glaciation. Three extensive sedimentary units dominate the regional geology: the Buzzards Bay and Sandwich Moraines, and the Mashpee Pitted Plain. The Buzzards Bay and Sandwich Moraines lie along the western and northern edges of Camp Edwards, respectively. The Mashpee Pitted Plain consists of fine to coarse-grained sands forming a broad outwash plain and lies between the two moraines. The land surface is generally flat with topographic highs in the area of the firing ranges, which are located on or near the moraines. Bedrock is encountered at depths of 87 to 111 m below ground surface (bgs) and is considered an impermeable layer (AMEC 2003a). Therefore, regional groundwater flow is transmitted though the upper outwash units. Unconsolidated deposits within the saturated zone exhibit a coarsening upward sequence (lacustrine, bottomset, foreset, and topset sedimentary facies) consistent with a glacial depositional environment (Masterson *et al.* 1997). Lithologic material varies from very coarse sand and gravel at the top of the saturated zone to silt and clay at the bottom immediately above the bedrock impermeable layer. The aquifer system is unconfined (i.e. it is in equilibrium with atmospheric pressure and is recharged by infiltration from precipitation) and is bounded on three sides by the ocean, with groundwater discharging into Nantucket Sound on the south, Buzzards Bay on the west, and Cape Cod Bay on the north. The Bass River in Yarmouth forms the eastern lateral aquifer boundary.

The SARs and Impact Area lie directly over the Sagamore Lens, a major groundwater recharge area and the most productive portion of the Cape Cod Aquifer. The apex of the Sagamore Lens is located at the southeast corner of the Impact Area from which groundwater flows radially in all directions. The thickness of the unsaturated zone varies from 18 to 37 m across most of the saturated zone. The average hydraulic gradient in the Impact Area is 0.003 m/m (AMEC 2004). Hydraulic conductivity is estimated to range from 38 to 107 m/day based on grain size analysis and aquifer tests (Masterson *et al.* 1996, AMEC 2003b) with an effective porosity of 0.39 (AMEC 2003b). Groundwater flow velocities across the Impact Area are estimated to vary from 17 to 61 m/yr (AMEC 2004).

The unconsolidated deposits in the unsaturated zone consist of very coarse sand and gravel associated with topset and foreset sedimentary facies. Surface water runoff is limited to a few hundreds of feet at most because of the highly permeable nature of the sand and gravel underlying the area.

2.4.3 Geochemistry of the Soil and Groundwater

Geochemical conditions are critically important with respect to assessing the fate-and-transport of lead and the potential corrosion of spent projectiles. Geochemical conditions can be broadly assessed by considering redox potential or Eh, pH, the identity and concentration of soluble salts, the organic carbon content of soil and groundwater, and the CEC of the soils.

Evidence examined to date indicates soil and groundwater conditions are aerobic (Table 2), although anaerobic niches or seasonally reducing locations certainly occur within such a large study area.

Table 2. Evidence for aerobic geochemical conditions of soil and groundwater at Camp Edwards.

Parameter	Premise	Test	N[1]	Result	Evaluation
Soil Texture	Coarse texture suggests aerobic conditions	Grain Size	64	Sands/Silt Loams	Relatively Coarse, Aerobic
Moisture Content	Low moisture content suggests aerobic conditions	Moisture by weight	64	Mean value 20% +/- 5.5	Moderate moisture content, Aerobic
Oxidation Reduction Potential	Highly positive measurements suggest aerobic conditions.	Measurement with platinum electrode	64	Median value ~300 mv	Slightly oxidizing
Concentration of Dissolved Oxygen in Groundwater	Presence indicates aerobic conditions, but several mg/L and higher indicates oxidizing conditions.	Field titration or electrode measurement.	>2,000	Values near saturation in shallow wells and several mg/L in deep wells.	Oxidizing
Resistivity	High resistivity indicates low soil moisture and aerobic conditions	Field measurements	64	Median value for initial resistivity ~ 70,000 ohms	High resistivity, Aerobic

[1]N = number of samples.

The pH may also govern the identity and mobility of the chemical species present. Most metal contaminants (e.g. copper, lead, and zinc) become increasingly mobile as the pH decreases. Soil pH at Maectite™ treated SAR impact berms ranged from 6.2 to 7.4 with a median value of 6.5. The ability of soil minerals to sorb contaminants from water is affected by competing ions

either in solution or already sorbed. Soluble salts are low as shown by the relative low specific conductance of the groundwater, typically 70 micro mhos per centimeter squared (umhos/cm^2).

Organic matter, whether from natural or anthropogenic sources may chelate with metals and enhance their mobility. However, organic matter content at Camp Edwards is low, and as shown by Cao *et al.* (2003a, 2003b), organo-lead complexes are most favored at alkaline, not acidic pH. As discussed in Appendix B, aluminum, iron, and manganese minerals present in soil and the aquifer are sufficiently present to limit lead mobility. Summaries of the metal content of soils in various areas of Camp Edwards can be found in AMEC (2001a, 2001b, 2001c, 2001d, 2001e, 2002a, 2003c) with typical soil concentrations of aluminum, iron and manganese ranging from several 1,000 ppm up to several 10,000 ppm (Ogden 1998a, 1999a, AMEC 2001a, 2001b, 2001c, 2003).

Cation exchange capacity (CEC) is an empirical measurement of the capacity of a soil to hold cations and exchange species of these ions in reversible chemical reactions. The low CEC (8-10 meq/100 g) indicates a low potential for sorption, but with respect to metal migration, the content of clay and hydrous oxides of iron and manganese are more important (Jenne 1968, Korte *et al.* 1976). Indeed, a study of aquifer material adjacent to Camp Edwards indicated strong correlation of lead adsorption with crystalline and amorphous iron and aluminum oxides (Fuller *et al.* 1996).

Aquifer geochemical conditions are an extension of those of the overlying soil. The coarse-grained unsaturated zone and coarse-grained aquifer material, in conjunction with the high precipitation rate (110 cm/yr), and relatively rapid groundwater flow rate cause conditions to be aerobic with a relatively low pH (~ 5.9) and a low concentration of soluble salts (AMEC 2004, 2001a).

3.0 Lead at Camp Edwards

3.1 Non-Military Training Sources of Lead

Studies at Camp Edwards demonstrate surface soils (0 to 0.3 m) samples collected from background locations range from 1 to 19 mg/kg (Table 3). The MassDEP lists several different mean background values which range from 15 to 100 mg/kg (MassDEP 2007) .The two most reliable background studies for metals in Massachusetts are likely to be a MassDEP (1995) study which determined a mean background value of 20 mg/kg based on 141 non-urban soil samples and a study of Massachusetts Licensed Site Professional subsurface soil data samples, which yielded a mean lead value of 15 mg/kg for 583 soil samples (Haley and Aldrich, 2001). The background values determined for Camp Edwards, therefore, are similar to the MADEP studies.

It is important to place lead in context with its principal sources and usual exposure pathways in order to understand its transport in the environment. Lead has a relatively high natural abundance (usually >10 mg/kg) with common soils ranging from 2 to 200 mg/kg (Lindsay 1979). Lead has become concentrated in the surface environment because of coal and oil burning and its use in paints and gasoline.

3.2 Military Training Sources of Lead

3.2.1 Soil Distribution at Camp Edwards

Several reports document the distribution of lead at Camp Edwards (Bricka *et al.* 1998, Ogden 1998a, 1998b, 1999a, 1999b, 1999c, AMEC 2001a, 2001c, 2001d, 2002b, 2003c). Over 9,000 soil samples have been collected and analyzed for lead across Camp Edwards to date (Figure 10) and when plotted indicate a sporadic distribution pattern with detections and elevated levels coinciding with the SARs (Figure 11). For the most part the reported lead levels in surface soils (0 to 0.3 m) are within the range of measured background levels for the site, although isolated areas of elevated lead are present. Elevated lead is somewhat related to target areas and firing lines (See also Tables 3, 4, and 5, Figure 11, and Section 2), but little or no migration to the subsurface is apparent, i.e. the frequency of lead detections and the concentration of lead decreases with increasing soil depth (Figures 12 and 13). Bricka *et al* (1998) studied G, H, and K Ranges and found lead was generally attenuated within the top 100 cm of soil with a few higher detections at depth. These studies were conducted prior to soil remediation activities. As part of the Lead Berm Maintenance Project, soils were treated in-situ and ex-situ with Maectite^{TM} (Table 4). Lead accumulation had occurred over several decades of range firing.

Certain locations have total lead concentrations exceeding action levels and guidance provided by both MassDEP and the USEPA. The locations (firing lines, berms) where lead is highest are consistent with firing range data obtained elsewhere. The maximum concentrations at Camp Edwards SAR (~12,000 mg/kg), however, are less than have been reported at other firing ranges (Zellmer and Schneider 1993, Cao *et al*. 2005), probably because most of the training at Camp Edwards has been conducted with bullets rather than lead shot. In addition, the active ranges were underwent berm maintenance in 1998 and training with lead projectiles has not resumed since, except for unapproved firing with lead on the J Range in October 2005.

3.3 Projects Specific to Camp Edwards Small Arms Ranges

3.3.1 Early Small Arms Range Studies

Prior to the Berm Maintenance Project, several SARs were studied by Bricka *et al*. (1998). Soil borings were collected from the G, H, and K Ranges. In general, all of the borings indicated relatively high levels of lead in the 1,000's ppm at the soil surface. The concentration of lead rapidly declined in all borings with background levels reached generally within 9 m. These borings did have elevated lead levels at greater depths. However, it is not apparent if these results represent lead migration from the surface or possible cross-contamination issues during sampling since these lead detections are sandwiched between samples with background levels of lead.

3.3.2 Berm Maintenance Project

In accordance with AO2, a SAR berm maintenance project was undertaken at Camp Edwards in 1998 by the MAARNG as a pollution prevention measure (Ogden 1999a). The objective of this innovative technology project was to protect groundwater by removing bulk metallic lead in the form of spent munitions from berm soils and immobilizing any remaining lead (Table 4).

To characterize the nature and extent of lead in the SAR soils, samples were collected from the up-range berm face and range floor (within 3 m of the toe of the berm slope) at active ranges. Sampling locations were established at 25-m spacing along the face of each berm and samples were collected in 0.6-m intervals to a depth of 2 or more meters. The samples were analyzed for total lead and leachable lead using toxicity characteristic leaching procedure (TCLP). A subset of these samples was also analyzed for total copper, iron, nickel, and antimony. A cumulative 1,125 samples were ultimately collected from the ranges (Ogden 1999a). Table 4 lists the number of berm samples collected by range.

In accordance with the screening criteria, soils exhibiting TCLP lead concentrations exceeding 5.0 mg/L would ultimately require treatment. The highest reported concentrations are listed by range in Table 4. In general, TCLP lead concentrations were greatest in the upper 1 m of the berm face (Ogden 1999a), which is consistent with the presumed penetration depth of small caliber projectiles. Elevated concentrations at depth were attributed to past reworking of berm materials during range maintenance and reconstruction activities. Based on the TCLP results, Current A, B, C, D, E, G, H, I, J, K, KD, N, O, and P Ranges were selected for treatment. Despite the absence of a berm backstop soil, soil treatment at the Southeast and Southwest Ranges was deemed necessary due to the presence of projectile fragments in soil mounds protecting pop-up target mechanisms there.

The treatment process consisted of an application of liquid reagent designed to permeate soil and immediately react with lead present. The reagent, Maectite^{TM} - a phosphate, was developed to chemically bond to lead within the soil matrix creating geochemically stable (i.e. less leachable) synthetic mineral crystals. For range soils with TCLP lead concentrations exceeding the 5.0 mg/L criterion, but exhibiting no visual evidence of metallic projectile fragments (e.g. on the range floor), treatment was performed in place. Approximately 5,380 cubic yards (yd^3)of soil was treated (Table 4) in this manner (Ogden 1999a).

Soils exceeding the TCLP lead criterion and exhibiting visual evidence of projectile fragments/jacketing were excavated from the berm faces and transported to central processing site. A total of 17,788 yd^3 of soil were ultimately excavated (Ogden 1998a); volumes treated from each range are presented in Table 4. At the central processing site, metallic munitions fragments were mechanically removed from the soils and stockpiled for off-site recycling. Processed soils were treated with the same lead-fixing reagent.

Post-treatment confirmatory samples were collected from both in-situ and ex-situ treated soils and tested again for TCLP lead. None of the post-processed soils exceeded the 5.0 mg/L performance value and 96% of these were less than one order of magnitude below that threshold, i.e. less than 0.5 mg/L (Ogden 1999a). After treatment, excavated soils were returned to the individual ranges for reconstruction of the berms.

3.3.3 IAGWSP Phase IIb Investigations

In 2002, investigation of environmental impacts associated with SAR training and other types of training at Camp Edwards continued in accordance with AO1 under Phase IIb of the IAGWSP (AMEC 2000, 2003c). Preliminary efforts under this investigation included a detailed review of archived range control log entries, examination of range layout maps and aerial photographs, and conducting additional reconnaissance site inspections at known SAR sites. Sampling plans were prepared for each range to provide a screening level assessment of residual soil contaminants associated with past training activities. The study focused on both up-range propellant-related contaminants and downrange projectile-related residuals.

Sampling began at the Former B, C, D, and the GA/GB Ranges. These currently inactive ranges are some of the earliest established SARs and each was used for a variety of different weapons types over several decades of training. Soil samples were collected from the firing points (when identifiable) and range backstops. At the Former B, C, and D Ranges, samples were collected from downrange hillsides that appear to have functioned as backstops. A small soil berm, presumably a remnant of the former range backstop, was discovered at the GA/GB Ranges. Discrete soil grab samples were collected at two depth intervals (0 to 15 and 20 to 61 cm bgs) at locations where projectile fragments were abundant at each of the four berm backstops.

Samples were analyzed for total metals and TCLP lead. At the firing point, five-point multi-increment soil samples were collected at three depth intervals (0 to 5, 5 to 15, and 15 to 30 cm bgs). Each sample was analyzed for total metals and semi-volatile organic compounds.

A similar sampling approach was used under a supplemental Phase IIb investigation of the 22 remaining SARs. Currently active ranges that were addressed during the berm maintenance project were included in the list of ranges tested (Tables 4 and 5). Downrange sampling at ranges treated during the Berm Maintenance Program was limited to regions beyond the treated backstop faces, and only where evidence of metallic projectiles was observed during pre-sampling site inspections. Sampling locations downrange at Former B, C, and D Ranges were selected to complement earlier Phase IIb sampling efforts. The total number of soil samples collected and analyzed under both Phase IIb investigations is presented by range in Table 5.

Analytical results for total lead in soil reveal that firing point concentrations at these ranges are generally not significantly elevated from the background range of values for Camp Edwards; however, there are some isolated elevated detections from discrete samples (Table 5). For downrange samples, total lead concentrations are highly variable, ranging from background to as much as four orders of magnitude higher. The highest concentrations of total lead were found in soil collected from Former D Range where projectile fragments were abundant. TCLP lead concentrations for samples collected from this range were similarly the highest observed (Table 5).

3.3.4 Tungsten Fate and Transport Study

Data for lead in Camp Edwards soil was also collected as part of a US Army Environmental Center (USAEC) funded tungsten study. The US Army Corps of Engineers, Environmental Research and Development Center, Cold Regions Research Engineering Laboratory (ERDC-CRREL) collected surface and subsurface soil samples from the B, C, and I Ranges. All of the surface soils were collected using a multi-increment, systematic random approach consisting of 100-increments collected over a 0 to 5 cm interval in the area of interest. The sample mass varied from 1 to 3 kilograms (kg). In surface soils, the highest lead concentrations were found on the berm face and the trough and declined towards the firing point. The lead levels at all three ranges are similar ranging from approximately 200 to 1,200 mg/kg. At B Range, lead levels in surface soils ranged from 24 mg/kg at the firing point to 1,200 mg/kg at the berm in the center firing lanes. At C Range, lead levels in surface soils ranged from 122 mg/kg for an integrated sample spanning the firing point, range floor, and targets to 1,090 mg/kg on the berm face. At I Range, lead levels in surface soils ranged from 91 mg/kg on the berm face to 815 mg/kg on the backside of the berm. The lower lead levels likely reflect soil berm maintenance activities which occurred in 1999, i.e. lead was physically removed from the soil and the soil was

treated with Maectite™. After the soils were treated training resumed with the tungsten/nylon round. Consequently, lead has not been introduced into the range soils post-treatment.

Soil profiles were prepared by collecting increments from four different soil cores. The soils from the same sample depth were combined to form a single sample. The sampling depth interval was 25 cm with one core collected using 5 cm intervals from B Range. The maximum sample depth varied from 75 to 150 cm. The termination depth was above the base of the berm except for those soil profiles collected in the trough. The sample mass varied from 5 to 20 kg for the subsurface soil. Subsurface soil data collected from the berm generally reflect a decline in lead concentrations with increasing depth for all three ranges studied. Lead concentrations at the termination depth were typically above the background range established for this study. An example from C Range is provided (Figure 14). Berm samples do not always show an obvious trend probably because the soil was reworked during remediation. A clear declining trend is evident for the trough sample which was not disturbed during excavation. .

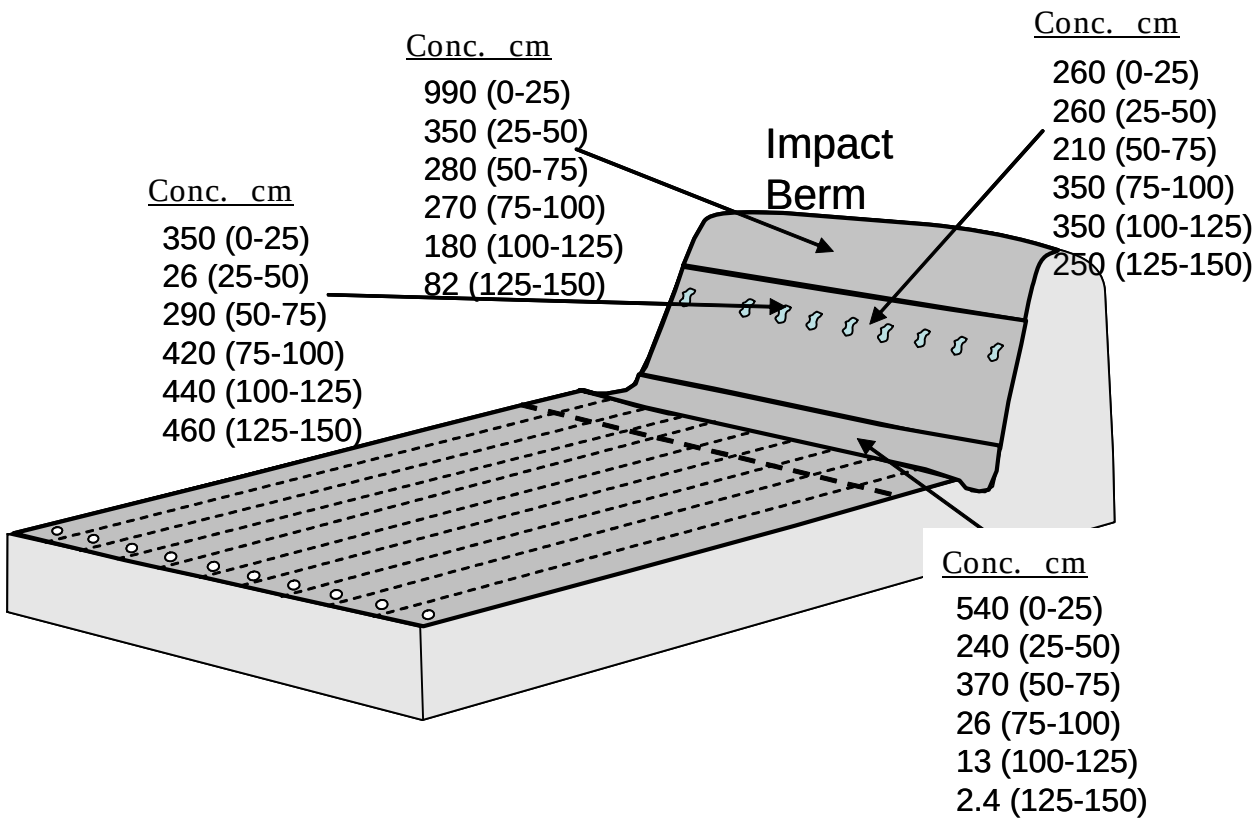

Figure 14. Lead soil concentrations (mg/kg) by depth (cm) at Charlie Range.

Four background samples were collected from a 50 x 50 m area, using the same sampling methodology as used on the SARs, away from the B, C, I, and M firing lanes. The background lead level for surface soil varied from 1.02 to 14.8 mg/kg with a mean of 5.9 mg/kg for this study, which is below the MassDEP defined state-wide mean of 20 mg/kg (MassDEP 1995), (see also Section 3.1).

3.3.5 Recent Small Arms Range Studies

More recently, multi-increment surface soil samples have been collected from E, SE, SW, and T Ranges. Lead levels ranged from 13 to 560, 10 to 180, 10 to 710, and 41 to 460 mg/kg at E, SE, SW, and T Ranges, respectively.

3.4 Corrosion of Spent Projectiles

Primary sources of lead at training ranges are spent projectiles and shot pellets. Thus, particle size and subsequent corrosion have a significant role in any ensuing lead migration. Small caliber military bullets (5.56mm [M16] and 7.62mm) leave residues that include chunks of metal, composed of antimony-hardened lead which can either be in a copper jacket or as a slug with masses ranging from 32 to 86 g per projectile, of which 96.4% by weight is lead (MIDAS 2007). These are relatively large chunks of metal and their low surface area inhibits both dissolution and biological availability. Moreover, soils at Camp Edwards do not significantly promote corrosion of metals despite the slightly acidic pH of 6.7 for the SAR soil, see Section 2.4.1.

There are two principal reasons corrosion processes are inhibited at Camp Edwards: lack of chloride and coarse soil texture. Chloride is the most important naturally occurring anion with regard to metal-corrosion and its content in Camp Edwards' soils and water is low. The mean chloride content of 61 soil samples collected from the Impact Area and evaluated in a corrosion investigation was 30 mg/kg (Chendarain and Stewart 2004). Six additional soil samples from Camp Edwards, collected and analyzed from the SE Range, had chloride concentrations ranging from 0.8 to 3.8 mg/kg. In contrast, various sources report approximately 130 mg/kg as the average chlorine concentration in the earth's crust (Korte 1999), with an average of 100 mg/kg for common soils (Lindsay 1979). Groundwater chloride concentrations at Camp Edwards are also low, approximately 10 mg/L. The latter value has been independently corroborated by a study reported for the shallow aquifer near Falmouth, MA where the ionic strength was reported as 28 mg/L (Fuller *et al.* 1996). Assuming approximately half of the ionic strength was contributed by chloride; the concentration at Falmouth also is approximately 10 mg/L. Savioe and LeBlanc (1998) report chloride levels of 15 to 20 mg/L for the tracer research site located south of MMR.

Pore-water chloride concentrations have not been measured to date, but are likely similar to the groundwater. The Camp Edwards chloride concentration in groundwater of 10 mg/L is less than the concentration required for pitting of stainless-steel (reported as 11 to 110 mg/L at pH 5 (Szklarska-Smialowska 1986), although one report said pitting might initiate at 4 mg/L at an unspecified pH (Bossia and Cragnolino 2000). Mendoza and Corvo (2000) identified chloride as the primary agent of aluminum corrosion. Chendarain and Stewart (2004) studied eleven aluminum fuses collected from Camp Edwards that exhibited little evidence of corrosion. Thus, while chloride may not be the primary agent reacting with lead itself, its scarcity in the Camp Edwards environment indicates a high resistivity in the soils which limits the corrosion of casings and metal alloys which may protect lead projectiles. Where the lead projectile is still encased in its copper jacket it is further protected from corrosion processes.

The second reason corrosion is limited is the effect of coarse soil texture on moisture content. This coarse texture influences the moisture content of soils, which is directly related to the corrosion rate of metal (Chendarain and Stewart 2004) including the increased galvanic corrosion that occurs when lead is jacketed by copper (Dermatas *et al.* 2004). The coarseness of the soil is demonstrated by comparing a triangular plot of sand, silt, and clay to the US Department of Agriculture (USDA) textural classification chart (Figure 8). One sample from each of the aforementioned 61 surface soil locations was used to assess soil texture. The majority of the samples classify as sandy loam, and, in decreasing order of prevalence, silt loam, loam, loamy sand, and sand. Such soils are very well-drained, therefore, despite a humid climate; surface soils have low moisture content thereby limiting corrosion and dissolution processes for spent projectiles on the soil surface.

3.5 Lead Solubility

The USAF issued a fact sheet nearly a decade ago, which described lead as relatively insoluble at neutral pH but also stating, "*as water becomes more acidic (decreasing pH), lead solubility tends to increase. When storm water (normally slightly acidic) comes in contact with lead contaminated soil, the lead can be dissolved into the water and transported to nearby groundwater or surface water. If sufficient lead is mobilized, environmental receptors can be affected and risk to human health could occur if these sources are used for drinking water. When groundwater is more than 10 feet below ground surface, it is generally not affected by leaching of lead from soil*" (USAF 1998). Although, the fact sheet is an oversimplification based on a few site-specific studies, it suggests acidic conditions at Camp Edwards could promote lead mobility. However, as discussed previously, several mitigating factors such as the lack of chloride and coarse soil texture limit corrosion of metallic lead and subsequent dissolution of lead oxides at Camp Edwards. The fact sheet also suggests ground and surface water would not be affected, i.e. surface water bodies are not located near the Camp Edwards SARs and depth to water is greater than 30 m. Although a generalization, the USAF fact sheet is

consistent with a recent, more detailed review by the ITRC (ITRC 2005) which listed the major reaction classes governing lead transport and fate as follows:

- Dissolution-precipitation as a function of pH,
- Dissolution-precipitation as a function of redox environment, and
- Sorption-desorption reactions.

The extent to which these reactions occur depends on site conditions such as soil composition, extent of soil saturation, and soil organic content. The Eh/pH stability diagram (phase diagram) and other figures presented in Section 2 demonstrate how the dissolution and mobility of lead derived from lead projectiles and shot are strongly influenced by pH, precipitating agents (e.g., carbonates, sulfates, phosphates, sulfides), and sorbents (e.g. iron and manganese oxides and hydroxides, organic carbon, clays) (Figures 4, 5, and 7). Common lead minerals which form in most soils decrease in the order of solubility as follows: $PbO > PbCO_3 > Pb_3(CO_3)_2(OH)_2 > PbSO_4 > PbHPO_4 > Pb_5(PO_4)_3OH > Pb_5(PO_4)_3Cl$ (Lindsay 1979). Phosphate exerts strong control on lead mobility, perhaps, explaining why lead has never been detected above 21 µg/L in lysimeters sampled in 2005 and 2006 located below lead-contaminated soil at the Bravo, Charlie, and India Ranges where Maectite™ treatment occurred (see Section 3.9 below).

Phosphate is not naturally present in sufficient concentrations to control lead mobility at Camp Edwards. Moreover, site data from TCLP indicate high lead solubility from some samples (see Section 3.8 below). Despite this fact, the latter test is unrealistic with respect to reproducing natural conditions; some amount of lead will dissolve in rainfall.

Thus, the low propensity for corrosion at Camp Edwards only means dissolution processes are relatively slow but not non-existent. Field and laboratory investigations have consistently reported elemental lead in shooting range soils becomes coated with cerussite and hydrocerussite (Lin *et al.* 1995, Astrup *et al.* 1999, Bruell *et al.* 1999, Lanndsberger *et al.* 1999, Hardison *et al.* 2004, Scheetz 2004, Vantelon *et al.* 2005). The latter mineral is also known as a common encrustation on native lead (AGI 1974) and both minerals commonly formed on lead fragments when subjected to alternate wetting and drying (Dermatas *et al.* 2003). For those shooting ranges with acidic soil pH similar to Camp Edwards, hydrocerussite (Scheetz 2004), cerussite, and small amounts of massicot (PbO) were predominantly present in the weathered crusts (Cao *et al.* 2003a). Massicot, the most soluble of the typical lead minerals, was not present at all ranges studied (Cao *et al.* 2003a, 2003b). These investigators calculated Pb^{2+} activities as supersaturated with regard to cerussite and hydrocerussite for both surface soil and berm soil at most locations. At one range, however, acidic soils rich in phosphorus contained hydroxypyromorphite [$(Pb_{10}(PO_4)_6(OH)_2$]—a very stable mineral again suggesting the addition of

phosphorus would provide an additional safety factor limiting lead mobility if added to soils at Camp Edwards.

3.6 Lead Sorption

When lead exists in a dissolved state, it can sorb onto iron and manganese oxides (Scheetz 2004) and to charged clay particle surfaces. On Cape Cod sediments, lead adsorbs strongly onto iron and aluminum oxides and poorly ordered allophonic (aluminosilicates) material, which occur as coatings on quartz grains (Appendix A, Coston *et al.* 1995, Fuller *et al.* 1996). Lead adsorbs extensively onto iron and aluminum oxides over pH ranges where these mineral have positive surface charge/potentials. In most natural soil environments, clays carry a net negative surface charge. In a solution having neutral pH, dissolved cations are sorbed preferentially. Therefore, when dissolved lead exists as Pb^{2+} in dilute solution, transport can also be attenuated by sorption to clays. These conditions occur in subsurface environments characterized by neutral to acidic pH, low dissolved solids concentrations, and low carbonate alkalinity — conditions similar to Camp Edwards. Although, Camp Edwards soils typically have a low clay content. In contrast, when dissolved lead exists preferentially as an uncharged ion pair or negatively charged hydroxyl complex, transport can be enhanced because sorption is negligible (presence of two negatively charged surfaces). These conditions can occur over a range of redox conditions but require alkaline pH, high total dissolved solids, or high carbonate alkalinity (ITRC 2005). The latter conditions do not exist at Camp Edwards (see Section 2).

The tendency of a solute (in this case, dissolved lead) to adhere to soil as it migrates is often presented as K_d. Larger values indicate increasing tendency for the solute to be retained by the solid phase. A K_d measurement of 34 L/kg lead was obtained for soils from the Impact Area at Camp Edwards (Larson 2007). Distribution coefficients measured for lead in a pH range relevant for Camp Edwards vary from approximately 900 to 9,000 mL/g (USEPA 1999) or for a sand 16,000 to 59,000 mL/g (Sheppard and Thibault 1990). Unfortunately, K_ds only describe solute partitioning between the aqueous and solid phases for a single set of environmental conditions. Such homogeneity does not exist in nature and greatly compromises the usefulness of the constant for calculation purposes. Therefore, measurements of Kd from multiple samples from a site are necessary to reflect accurately the intrinsic variability of soil properties. “For this reason, any comprehensive compilation of K_d values selected from the literature should be expected to present values that define a distribution” (USEPA 2005b). On the other hand, the range of values reported for sand and gravels with limited organic carbon demonstrates dissolved lead’s predominant propensity is to sorb to the soil. The K_d values reported above are large enough to predict sorption as a dominant process even in Camp Edwards’ soils where the quantity of clay is low. The results from a tracer test conducted at the USGS Toxic Substance Hydrology Research Site at Cape Cod, Massachusetts supports the higher K_d values rather

than the single sample measurement (Larson 2007) as demonstrated by the rapid attenuation of lead (Appendix B).

The concept described in the preceding paragraph has been demonstrated by many laboratory experiments, which also show a significant dependence on pH. For example, one study showed lead sorption was nearly 100% at pH 4 for grassland soils (mollisols) and highly-weathered soils high in iron oxides (oxisols) (Appel and Ma 2002). Sorption of lead remained greater than 60% under the same pH conditions for a soil with low base status (ultisol), analogous to soils found at Camp Edwards (Appel and Ma 2002). Similarly, work on three deep subsoils from the Nevada Test Site (Papelis and Um 2003) showed nearly 100% lead sorption even at pH 4 for two samples and >50% for the third. Finally, studies with aquifer material from near Falmouth, Massachusetts reported approximately 40 to 80% of added lead was adsorbed (Fuller *et al.* 1996) and a later field tracer experiment indicated 100% lead adsorption (Appendix A). All of these studies, except for those in Appendix A, were performed as batch reactions in test tubes representing only a single pass of liquid through a fixed volume of soil. In other words, if the supernatant liquid was removed and mixed once more with the same volume of fresh soil, the least efficient soil would remove > 50% of the remaining lead and so on with additional extractions. Thus, dissolved lead migrating through a column of even the least efficient soil would be approximately 100% sorbed after migrating only a short distance. An example of this behavior under extreme conditions was an experiment whereby more than 70 mg/L lead (a concentration far higher than is possible under any conditions possible at Camp Edwards) was passed into a sandy soil with low pH (4.2) at an infiltration rate of approximately 10 cm/day. (Camp Edwards' infiltration rate is approximately 75 cm/year (0.20 cm/day) (AMEC 2004, 2001a) which is relatively high for natural systems). Even under such severe conditions, lead was not observed in the leachate of a 10 cm column until approximately 50 cm of infiltration had occurred (Korte *et al.* 1975). The latter set of experiments compared 11 soils from seven soil orders and concluded lead was so immobile, even after 30 days of leaching, “from input-output data alone, differences due to soil properties could not be distinguished” (Korte *et al.* 1976).

Finally, an experiment specific to the Cape Cod, Massachusetts aquifer demonstrated lead’s relative lack of mobility. Lead complexed to an organic chelate was injected into the aquifer. Little migration occurred and dissolved lead was virtually all adsorbed near the injection location (Appendix A). Particularly striking was how much more rapidly lead was attenuated than zinc, copper, and nickel chelates (Davis *et al.* 2001). Similarly, an analysis of sewage waste leachate on Cape Cod indicated rapid attenuation of lead (Appendix A). In summary, the combination of geochemical conditions at Camp Edwards and lead’s own geochemical properties severely inhibit lead migration to groundwater. This conclusion is supported in the following subsections by considering site monitoring data.

3.7 Lead Bioavailability

As described in Sections 1 and 2, exposure to avian species must be minimized and there are a number of factors limiting exposure at Camp Edwards. Foremost are the lack of permanent or semi-permanent standing water (e.g. wetlands) near the SARs being considered for renewed military training and the small area encompassed by these ranges relative to the habitat available for the raptors and mammals present at Camp Edwards. Finally, the Natural Resources Manager at Camp Edwards has observed no evidence of raptors, mammals, reptiles, or biota being affected by lead on the SARs (MAARNG 2006). Nevertheless, it is acknowledged that specific studies with biota have not been performed and that animals dying after lead ingestion are seldom found. Small mammal trapping data, however, indicates healthy populations exist within the range areas and there has been no indication that there should be a concern in regards to lead causing the death of such organisms.

3.8 Soil Lead Leachability

Some selected data from SARs at Camp Edwards are presented in Tables 1, 3, and 4. Table 1 describes range history and Tables 4 and 5 show lead accumulation at firing lines, backstops and berms. Tables 4 and 5 include a “leachability ratio” as defined by Dermatas et al. (2006). This ratio is calculated by multiplying the TCLP result by 20 and then dividing by total lead. The TCLP method employs a 1/20 dilution of the sample as part of the USEPA Method 1311 (USEPA 2006). If the subsamples used for the total and TCLP analyses are identical, 100% leachability indicates all of the lead was leachable by TCLP.

High lead leachability under the TCLP is commonly found with shooting range soils. Dermatas *et al.* (2006) studied four army rifle ranges and reported lead carbonate precipitation/dissolution reactions controlled lead TCLP leachability in all soils. They also reported, as with some Camp Edwards data (Tables 4 and 5), virtually all of the lead was leachable (for a soil with pH of 4.2) under the TCLP in several soils. As the previous subsections (e.g. 3.6) and Appendix A show, sorption processes limit lead mobility no matter how much dissolves. Section 3.12 below further illustrates high leachability under the TCLP does not correlate to significant lead migration in the subsurface. This has been substantiated for Camp Edwards soils under laboratory conditions using lysimeters, which found no appreciable dissolved lead even though more than 1,000 mg/kg of lead was present in the soil and the column thickness was less than 0.6 m (Larson et al. 2007). Although, the TCLP is a standard test used for leachability as noted above it typically does not provide an accurate reflection of the behavior of constituent under site conditions. Therefore, greater confidence should be placed in the column leaching experiments conducted by Larson at al. (2007) and the field tracer tests conducted by the USGS (Appendix A) than the TCLP results.

Lead is heterogeneously distributed even at firing lines and impact areas. This fact is demonstrated by the significant variation in leachability (Tables 4 and 5) and the scattered distributional pattern in soil (Figure 11). A few leachability values exceed 100%. Such variations are probably a result of subsampling where the sample for total analysis and the sample for TCLP were not identical. For instance, a sample may have a high total lead concentration because of the presence of a single bullet fragment. Even though the sample might have been well-mixed, a subsample taken for TCLP may be absent of lead added by training, thus accounting for the large differences observed.

Data from the Former B range is unique for Camp Edwards, because there was a sediment depositional area at the base of a berm impacted by training. In this case, the highest concentrations of lead, copper, and antimony were detected in soil collected from a low-lying depositional area located at the base of a hillside backstop (AMEC 2003c). Concentrations of the same metals at locations higher in elevation on the hillside and nearer the former targets were lower by an order of magnitude. These data demonstrate localized soil erosion and surface runoff can concentrate lead and must be managed on an active range. It is not known, however, whether this lead deposition at the Former B Range was a result of particulate erosion or dissolution followed by precipitation.

3.9 Lead in Pore-Water

In addition to the soil samples discussed previously for the tungsten study, which were treated with Maectite™, 24 tension lysimeters were installed within and below the berm face at the B, C, and I Ranges, as well as at three background locations. Tension lysimeters collect soil-pore water derived from precipitation events as it moves through the unsaturated zone. Lysimeters were sampled four times (10/20/05, 11/9/05, 12/17/05, and 5/10/06) and the water samples were analyzed for lead as well as other metals (USAEC 2006). The depth of the lysimeter tip varied from 38 to 165 cm bgs. The first round of samples were analyzed by Inductively Coupled Plasma Atomic Emission Spectroscopy (ICP-AES) with a corresponding reporting limit of 0.050 mg/L and by Inductively Coupled Plasma Mass Spectroscopy (ICP-MS) with a corresponding reporting limit of 0.002 mg/L. The detection limit for both of these is approximately 1/10 of the reporting limit. Samples collected on 11/9/05 and 12/17/05 were analyzed with the ICP-AES. The final rounds of samples collected on 5/10/06 were analyzed with the ICP-MS and through some method modifications, the reporting limit was lowered to 0.001 mg/L. Also, as mentioned previously, the B, C, and I berms had been treated with Maectite™. This phosphate-based material will combine with any dissolved lead present to form a sparingly soluble lead phosphate. Without further study, it is not apparent whether natural geochemical conditions, Maectite™, or a combination is limiting lead movement. The IAGWSP is planning to install several lysimeters at the Former D Range, an untreated range, to assess further lead mobility.

Lead was detected in samples taken from the lysimeters with the highest reported concentration of 0.021 mg/L on 5/10/06 at MMR-18 located on C Range at a depth of 117 cm for an unfiltered sample (Table 6). Analysis of the data indicates no pattern of detection by range, depth, or soil concentrations.

Table 6. Lead concentration in soils and lysimeter samples collected from Bravo, Charlie, and India Ranges.

Lead was detected in two of the background lysimeters sampled on 5/10/06 at 0.001 mg/L for MMR-27 and 0.002 mg/L for MMR-15 (USAEC 2006). The source of the lead in the background lysimeter samples is undeterminable when solely relying on the pore-water data. Therefore, lead could be the result of natural conditions or anthropogenically-derived from airborne deposition of particulates from propellants at the firing line. However, soil samples from the firing line indicate slightly elevated lead levels as compared to the background lead soil samples.

These background soil samples are located in the woods near the lysimeters. Also, one background soil sample was collected from a remote area near M Range and the lead levels were the same as those of the background samples from B, C, and I Ranges. Therefore, the soil data indirectly suggests the lead measured in the background lysimeters probably has its origin in the native soil. Background soil samples had lead present at concentrations ranging from 1.02 to 15.8 mg/kg. As discussed previously, the geochemical conditions at Camp Edwards do not favor dissolved forms of lead being present to any significant degree. This is supported by the lysimeter and soil profile data which indicates any dissolved lead species derived from corrosion and dissolution of metallic lead is rapidly removed from the soil pore-water through adsorption and precipitation processes.

3.9.1 Lead in groundwater

Consistent with the preceding discussion, lead has been reported in 24 of more than 500 groundwater samples. Most of these groundwater samples were not collected from monitoring wells located downgradient of SARs but rather associated with the Impact Area. As discussed in Section 3.2.1 the highest lead soil concentration observed, approximately 12,000 mg/kg, was found in the Impact Area near an artillery/mortar target. However, lead has been detected in four monitoring wells out of over 60 located within the Impact Area and downgradient of the target locations. Elevated soil lead levels are also evident at Demolition Area 1 (Demo 1) (AMEC 2001a), again with over 20 downgradient monitoring wells not exhibiting the presence of lead (AMEC 2001d).

Recently, 13 monitoring wells were installed specifically to monitor groundwater downgradient of the SARs (black dots on Figure 15) at the B, C, G, K, J, Former B, SW, and T Ranges. The first two rounds of samples collected from these wells were non-detect for lead at the 0.003 mg/L reporting limit. The detection limit for the groundwater samples collected and analyzed by the IAGWSP was approximately 0.0003 mg/L or $1/10^{th}$ of the reporting limit. The berms at the Former B and D Ranges have not been remediated whereas the B, C, G, K, J, T, and SW Ranges have been remediated with metallic lead removed and the soil treated with Maectite™. These results indicate lead has not migrated to groundwater at any of the ranges. At the Former B and D Ranges, training with lead ammunition began in 1935 so these data represent the impact of approximately 60 years of lead use. These findings are consistent with the previous Section on lead adsorption as well as the USGS Tracer and Sewage Effluent Studies (Appendix B) indicating limited lead mobility. The lack of lead in groundwater derived from the small arms firing ranges is supported by independent unsaturated zone modeling efforts discussed in the following section. These wells were drilled at several ranges and sampled between September 2006 and November 2006 by three separate organizations working at Camp Edwards: IAGWSP, Environmental and Readiness Center (E&RC), and USAEC. All locations were approved by the USEPA and MassDEP prior to installation. The IAGWSP installed wells to

investigate the potential impacts to the groundwater from soil contaminants resulting from past use of the SARs. The IAGWSP selected locations based primarily on frequency of use so that the most heavily used ranges were investigated. The E&RC installed wells to be included in their pollution prevention program (E&RC 2006). It is the authors' judgment that these wells are adequate for assessing whether lead has migrated from the SARs to groundwater. Additional groundwater data will be forthcoming as these wells are sampled in the future.

In addition, well MW-72S was installed as part of the Berm Maintenance Project to monitor groundwater quality downgradient of a typical treated berm (Current B Range) in 2000. Groundwater samples have been collected from this well during 13 rounds of sampling and lead was reported only once, at 0.0014 mg/L in a filtered sample.. The unfiltered sample for this same sampling event contained no detectable lead. Samples previous to and subsequent to this single detection indicated no lead at present at the 0.001 to 0.003 mg/L reporting limit. This well is located approximately 10 m downgradient of the berm backstop, near the center of the B Range firing lanes, and near the location of some of the highest soil lead levels. Consequently, if lead was being transported to groundwater this is one of the monitoring wells most likely to show it. Lysimeters located near MW-72S also exhibit sporadic detections of lead with the highest concentration observed being 0.021 mg/L. The basis for these sporadic detections in both the monitoring well and lysimeters at Current B Range are not fully understood and further investigation of this issue are beyond the scope of this study. However, additional monitoring will be conducted of both monitoring wells and lysimeters to further evaluate these detections.

Monitoring well MW-174 was installed at the end of the Phase IIb investigation in 2001 at the Former D Range to monitor groundwater quality directly beneath soil exhibiting up to 4,200 ppm total lead at this rannge. In the process of drilling the borehole for this well, soil samples were collected at 3 and 6 m bgs to examine lead concentrations at depth. In both samples, total lead concentrations were approximately one order of magnitude less than MassDEP mean background level of 19 mg/kg. A single well screen was installed at the water table. Groundwater samples were collected from the well during three sampling rounds and lead was not detected in any of them.

Background levels of metals in groundwater and pore water have not been established for Camp Edwards. However, as discussed in the proceeding section, background soil pore-water lead levels range from 0.001 to 0.002 mg/L (USAEC 2006). For comparison, the USEPA Action Level for lead in public drinking water supplies is 0.015 mg/L. Detections elsewhere at MMR have also been sporadic and low-level (Ogden 1998a, 1998b, 1999a, AMEC 2001f, 2004). Nonetheless, any migration of lead to Camp Edwards' groundwater would be problematic and any detection in groundwater seems to contradict lead's geochemical behavior as described in this report. It is possible that some of the detections of lead in groundwater at MMR may be due to lead's ubiquity in the environment and interferences during analysis. For example, Figure 14

presents lead detection by date for those wells with more than two reported “hits” for lead. There is an apparent relationship with date suggesting a problem encountered with much less frequency either before or after roughly March 1999 to March 2003. Early in the IAGWSP study, monitoring wells were sampled by bailers and later dedicated bladder pumps were installed. Research by Kearl *et al.* (1992) has shown sampling with bailers typically increases turbidity of water samples, which could explain some of the detections during the period of note. Other issues may also be responsible for these sporadic detections. Well construction details are lacking for the ASP, Textron, and Cemetery wells. The BHW well is constructed of galvanized steel and MW-45S was installed within a known NAV Gas plume which apparently contains tetraethyl lead from the fuel. Finally, none of these wells is located close enough to a SAR to have been impacted by lead migrating from the range (Figure 15). Note the wells depicted with black dots on Figure 15 have been recently installed and sampled once with no detectable lead reported.

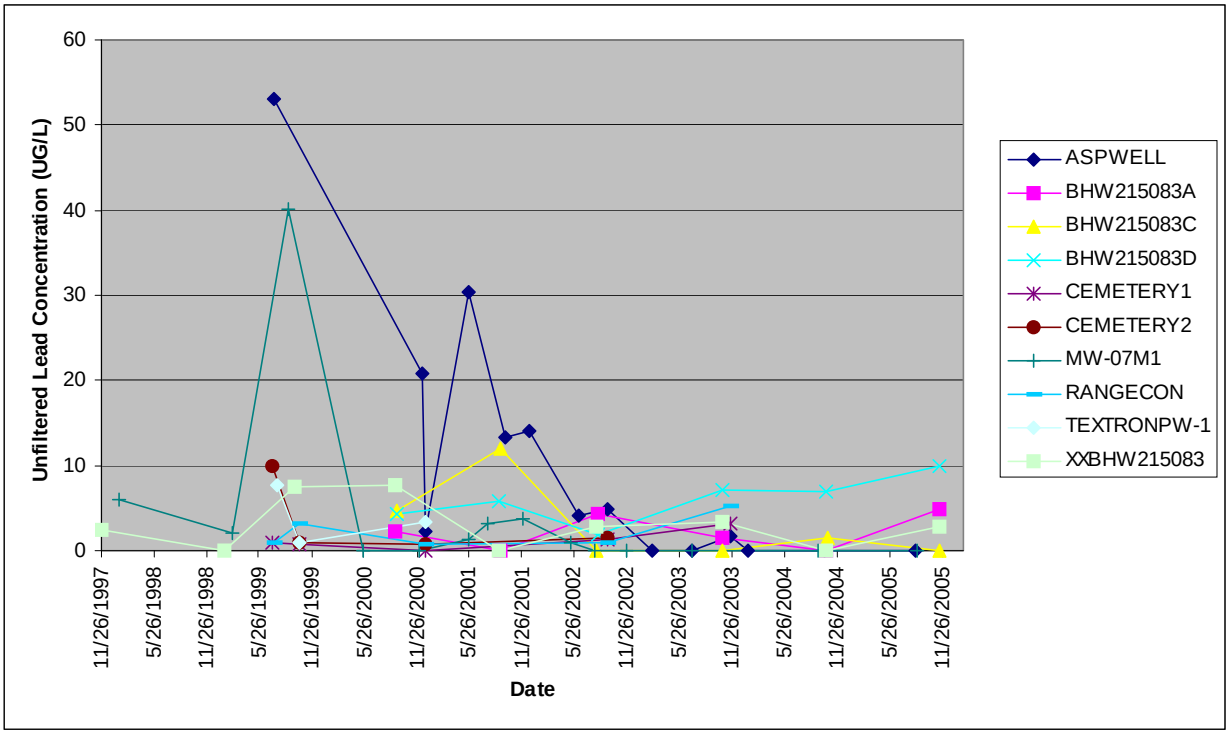

Figure 14. Unfiltered lead in groundwater where wells having more than two detections.

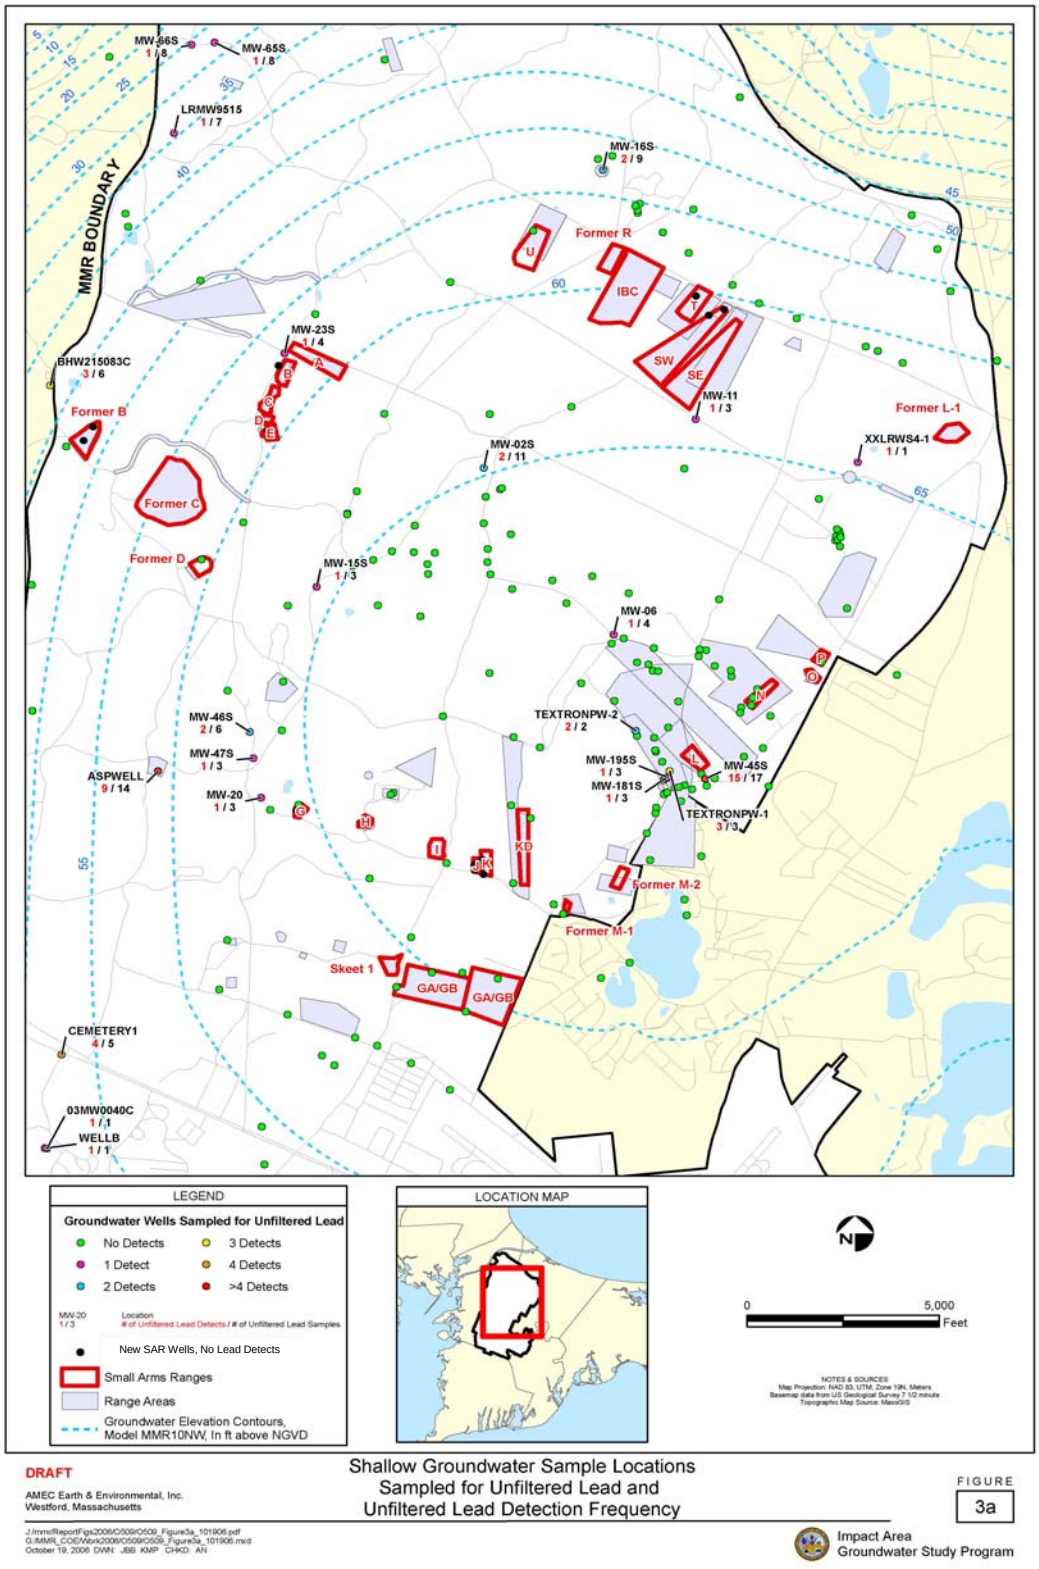

Figure 15. Shallow ground water detections of unfiltered lead.

Unlike the circumstances with synthetic organic compounds where false positive detections are rare, finding traces of lead in water samples where the lead is not indicative of groundwater conditions is relatively common. For example, USEPA Method 200.7 (USEPA 2006), "Determination of metals and trace elements by inductively coupled plasma atomic emission spectrometry" includes a discussion of spectral overlap but says only that overlap "may" require selection of an alternate wavelength. Accurate correction is left to the judgment of the analyst without further explanation. The procedure also notes that physical interferences may occur and their magnitude is related to the identity and quantity of dissolved salts in the sample. Thus, both physical interference and spectral overlap may also be responsible for some of the sporadically reported lead in MMR groundwater. This suggestion is advanced solely for those wells where lead has been reported sporadically. Figure 16 compares unfiltered lead concentrations to turbidity for MW-02S. This is a small data set and is not representative of the entire data base of turbidity versus lead detection. These results, however, show elevated unfiltered lead correlated with high turbidity. Turbidity is a measure of suspended material, which often consists of aluminosilicate clay particles having various metal species sorbed to the clay surface (e.g. iron, lead, manganese, etc.). The presence of lead could be the result of adsorption onto clay particles however, a mechanism is lacking for the introduction of dissolved lead at depth due to the sportive capacity of Camp Edwards soil and the likelihood of formation of relatively insoluble precipitates (Appendix A). Facilitated or colloidal transport has not been demonstrated in the lysimeter samples installed as part of the Tungsten-Nylon Small Arms Range Assessment based on filtration experiments (Clausen *et al.* 2007). Figure 17 shows many elevated lead values correlate to iron, which suggests the elevated metal concentrations are derived from a natural source. Due to the sample preservation technique of using nitric acid, per USEPA Methods, suspended metals present in the unfiltered sample may be dissolved and be detectable during analysis. High iron is another potential cause of analytical error because it has so many spectral lines which offer the opportunity for problems with spectral overlap. Thus, both physical interference and spectral overlap are implicated as potentially responsible for some of the sporadically reported lead in MMR groundwater.

It is also not necessary to invoke interference for sporadic lead detections. Lead is relatively abundant in soil/sediments. The fact a sample has high turbidity indicates there is a great deal of undissolved soil material in the sample. Similarly, inadvertent inclusion of microscopic dust during sampling or in the laboratory could also contribute to sporadic lead detections. As noted elsewhere in this report, natural soil contains lead and thus may account for the traces reported in wells where lead has been reported sporadically.

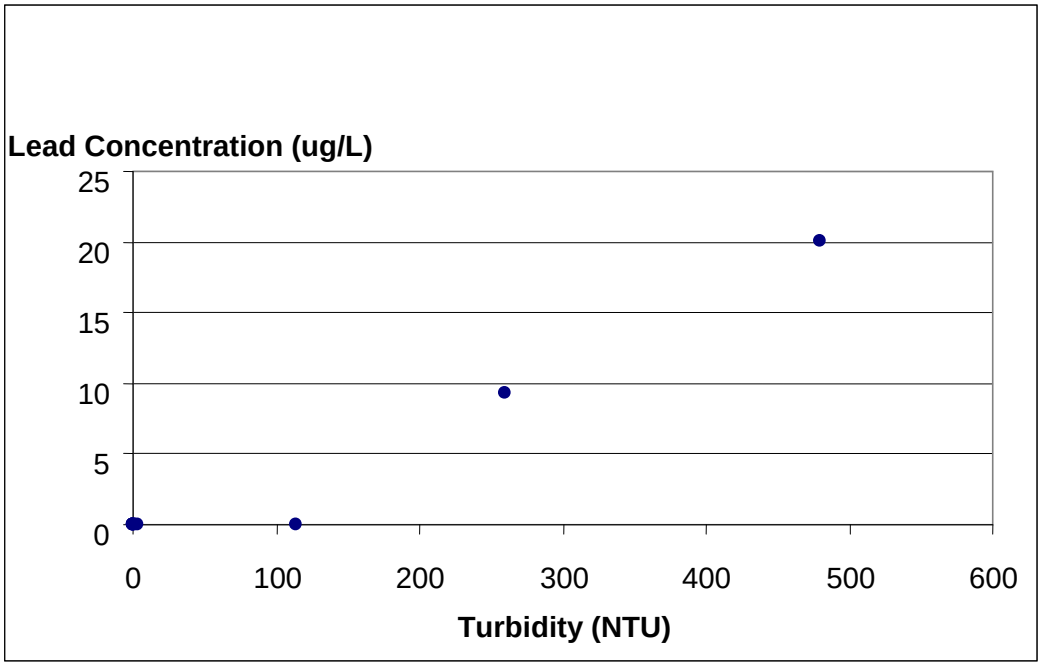

Figure 16. Unfiltered lead versus turbidity for monitoring well MW-02S.

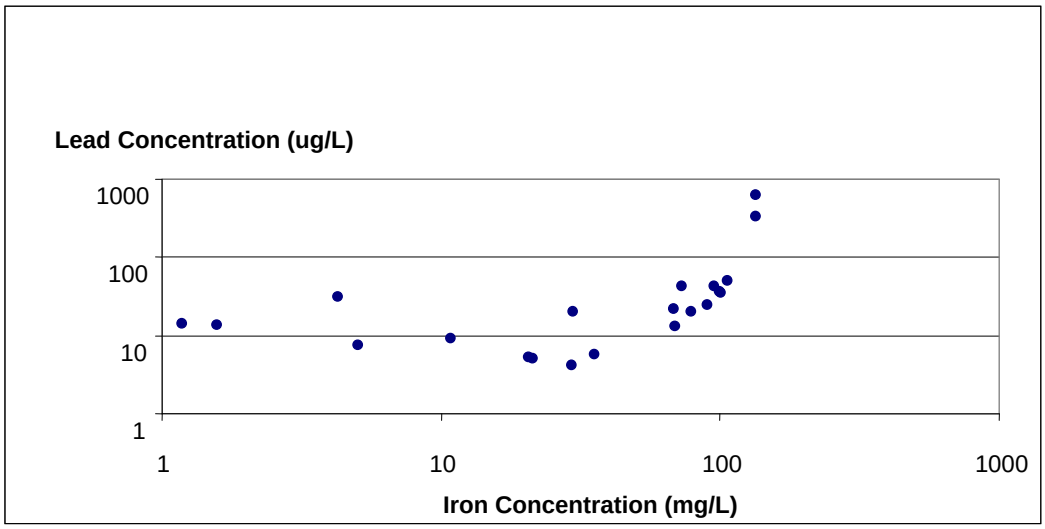

Figure 17. Unfiltered lead versus iron (log scale). Data obtained from Impact Area Ground Water Study Program, Electronic Data Management System database.

The most important rationale for discounting sporadic lead detections in groundwater, however, is the low number of detections and many are sporadic, i.e. not reproduced in multiple sampling events from the same well. Finally, the wells with the lead detections are not associated with the known primary lead sources. The few detections support the geochemical arguments advanced regarding lead's low propensity to migrate to groundwater under the geochemical conditions at Camp Edwards. This fact is supported by a review of the lead in groundwater data as presented previously in Figures 14 and 15. These data demonstrate lead is not consistently detected and when it is reported, the value is typically well below the drinking water standard. (Appendix B, Ogden 1998a, 1998b, 1999a, AMEC 2001a, 2001d, 2003c). The low percentage of lead values reported in Camp Edwards' groundwater is consistent with any large sampling program where many samples are analyzed and some are high in iron or turbidity.

3.10 Modeling Lead Mobility

The potential for lead migration at Camp Edwards was modeled in 1998 (Bricka et al. 1998). This study used conservative assumptions, many of which can now be substantially refined. While this study clearly over-predicted lead mobility, it provides a useful point-of-departure for examining lead migration under more realistic conditions and for considering range maintenance measures. Although the quantity migrating was small, Bricka et al. (1998) suggested lead could migrate to groundwater in 150 to 300 years. The authors recognized their assumptions would over-predict lead migration, but recommended soil clean up every 50 to 70 years as a means of preventing groundwater contamination. To put this study in perspective, it is useful to compare some of their assumptions with facts known today:

All the lead was assumed available for transport as soon as it was deposited. In contrast, the corrosion discussion in this document shows rapid oxidation of deposited lead is not favored. Moreover, most lead-containing particles will be large and possibly jacketed with copper, which will prevent much of the lead from being available for corrosion and dissolution.

The study assumed all of the lead was in the form of a highly-soluble salt and, therefore, was all available for transport. As described previously in this report, lead salts will form following corrosion, but none of these salts is highly soluble. Moreover, if phosphate is added to the soil, the salts can be considered essentially insoluble with respect to migration in water.

Because of the difficulty of performing unsaturated zone modeling, the entire unsaturated zone was assumed to be saturated. Furthermore, alternate wet and dry cycles and the low moisture content of Camp Edwards soils was not considered, which significantly inhibit both corrosion and dissolution.

Bricka et al (1998) assumed a retardation factor for lead of 50 or a K_d of approximately 10 mL/g, which is more than a factor of three less than the value of 34 mL/g recently measured by Larson (2007) for a sample collected from the Impact Area at Camp Edwards. Both values are 1 to 2 orders of magnitude lower than the USEPA (1999) K_d recommendation of 900 to 9,000 mL/g for soils similar to Camp Edwards or the range provided by Sheppard and Thibault (1990) and Thibault et al. (1990) of 16,000 to 59,000 mL/g. Bricka et al. (1998) calculated centuries would be required until the sorptive capacity of the soil would be exhausted. The field studies of the USGS (Appendix B), soil profile, and soil pore-water data suggests the soil has a very large sorption capacity for lead. This prediction, therefore, is certainly too low based on the lowest value for K_d either as measured or as recommended by the USEPA. Finally, it should be noted this modeling is an oversimplification because pH and not K_d is probably a more important factor regarding lead transport.

As is described previously in the Soil Pore-Water subsection, one response to the predictions and assumptions of Bricka et al. (1998) is to monitor the ranges with lysimeters placed below lead accumulation areas. Should lead be detected, range maintenance can be conducted. Such practices are still conservative. Indeed, to ensure against lead migration to groundwater, the addition of phosphate (e.g. Maectite™) to the soil will result in formation of lead salts which are nearly insoluble; thus significantly enhancing the sorptive capacity of the soil.

Investigators at Camp Edwards have also employed the Seasonal Soil Compartment Model (SESOIL)—a one-dimensional finite-difference vertical transport code for simulating contaminant movement in the unsaturated soil zone (Bonazountas and Wagner 1984, Hetrick *et al.* 1993). SESOIL was designed as a screening-level tool, utilizing less soil, chemical, and meteorological input data than most similar models. The model can simulate water movement, sediment transport, and pollutant fate (i.e. degradation), and can be applied to generic environmental scenarios for purposes of evaluating the general behavior of chemicals in the unsaturated zone. SESOIL is designed to estimate contaminant concentrations in the soil following direct application at the surface and/or interaction with other media. Modeling results for lead were conducted for the Impact Area (unpublished), Gun and Mortar Firing Positions (AMEC 2001e), Demo 1 (AMEC 2001f), and for the SARs (AMEC, 2002a). The Impact Area, Gun and Mortar Firing Positions, and Demo 1 modeling indicated vertical migration of less than 1 m over 100 yrs using the maximum surface soil concentration observed. The maximum lead soil concentration used in the model for the Impact Area was 148,000 mg/kg, more than ten times higher than the maximum concentration measured at the SARs of 11,600 mg/kg. The unsaturated zone geochemical conditions at Demo 1 and Impact Area are similar to those at the SAR. Model simulations suggest travel times on the order of many centuries before lead reaches the aquifer.

More recently, SESOIL was used to simulate lead movement at the SARs (USACE 2007). Using a K_d value of 270 mL/g, as obtained from a risk assessment data base maintained by the Department of Energy, this exercise predicted lead would not reach the water table in 999 years. This simulation used a water solubility of 4,250 mg/L which, as described in Section 3 of this report, is unrealistically high.

In these simulations, the model was primarily considering sorptive reactions and did not consider precipitation reactions. In addition, the SESOIL model does not include input functions that can account for the oxidation and precipitation of metals or the dissolution kinetics going from a solid to aqueous phase. Consequently, based on the previous discussions the models over predict lead migration.. Furthermore, a sensitivity analysis included in the impact area and Demo 1 modeling found the SESOIL model predictions most sensitive to the following parameters:

Transport Rates - The largest area of uncertainty in unsaturated zone modeling is the relationship between the mass of the material of interest and mass flux from surface soils through the unsaturated zone to the aquifer. Sensitivity analysis with hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX) indicates SESOIL over-predicts RDX movement and subsequent groundwater concentrations. Similarly, SESOIL will over predict lead movement and resulting groundwater concentration since the key factors controlling transport in SESOIL are precipitation and solubility and K_d of the constituent of interest. Just as with RDX, the lead dissolution rate is a complex function of particle size, temperature, moisture, and geochemical conditions. Several of these variables such as dissolution rate and particle size of the constituent of interest and soil geochemistry are not considered in the SESOIL model.

Concentrations In Unsaturated Zone Soil Moisture - The concentration of lead or other constituents dissolved in soil moisture in the unsaturated zone has not been measured at untreated SAR. Thus, the concentration migrating has to be estimated. The literature review and lysimeter data presented herein suggests there may be no lead migrating more than a meter. Thus, any estimate of lead migration through the unsaturated zone almost certainly results in an over-prediction.

Unsaturated Zone Migration Rates - The hydraulic travel time through the unsaturated zone has not been quantified. Because it is not known how long it takes soil moisture to travel from the soil surface to the water table, it is not known how long it will take for materials to flush out of the unsaturated zone.

Groundwater Mixing Zone - The mixing zone thickness increases with distance from the source, but the approximate thickness in the vicinity of the source is not known.

These uncertainties coupled with reliance of existing models on K_d suggest the utility of transport models such as SESOIL to simulate lead movement is limited. Presently, there are no existing transport models that can accommodate corrosion and dissolution of a metal solid species.

In summary, a qualitative evaluation of lead migration suggests it could take centuries for lead to migrate to groundwater at Camp Edwards. A review of previously-performed modeling suggests the uncertainties in modeling lead migration are very large and the results over-predicted lead transport in one case. In the other case, modeling results suggested lead would not move appreciably from the SAR. Considering a key uncertainty is the concentration in unsaturated zone moisture, sampling with lysimeters is likely a very useful means of evaluating whether lead migration is occurring or whether the qualitative review indicating significant migration will not occur is sufficient. As discussed earlier, the lysimeter data for ranges treated with Maectite™ primarily indicates no lead is present in the soil pore-water and when present the levels did not exceed 0.021 mg/L. The planned installation of lysimeters at the untreated Former D Range should provide useful data for validating the model output.

3.11 Other Constituents in Lead Ammunition

There are other potential constituents (ITRC 2005) associated with use of lead at firing ranges (Table 7). A fate and transport discussion of these elements is beyond the scope of this report but Table 7 is provided for completeness. The IAGWSP plans to address the presence of metals at the SARs through a remedial investigation. Several constituents were removed from the original table (e.g. tungsten) because those are not going to be used in the forthcoming training.

Table 7. Metallic contaminants associated with outdoor shooting ranges (modified from ITRC 2005).

Constituent	Comment
Lead	Primary projectile constituent, primer constituent, and present in initiators and propellants
Arsenic	Used to increase roundness of small shot
Tin and antimony	Increases hardness, Sb used in some primer compounds
Copper and zinc	Jacket alloy metal
Cobalt and chromium	Some military rounds
Nickel	Coating improves shot performance

As noted previously, small caliber military bullets (5.56 mm [M16] and 7.62 mm) have spent projectiles composed of antimony-hardened lead in a copper jacket with masses ranging from 32 to 86 g per bullet, of which 96.4% by weight is lead (MIDAS 2007). Thus, the other constituents are relatively minor in terms of mass when compared to lead. Some in this list also may not be relevant. Arsenic and nickel are primarily used in shot, and tin, zinc, chromium, and cobalt are present mostly as impurities. Arsenic, antimony, copper, nickel, and zinc were consistently detected in the lysimeters installed at the three SARs as part of the Tungsten Fate-and-Transport study; however, the background lysimeters also had detections of these metals at similar levels. Chromium was not detected in any of the lysimeter samples, with the reporting limit at 0.001 mg/L. These minor constituents are subject to the same corrosion processes as lead but neither copper nor zinc is nearly as toxic. Copper's drinking water standard is 1.3 mg/L. Zinc has only a secondary standard (5 mg/L) meaning the primary concerns are taste and color.

3.12 Comparison of Camp Edwards with Other Small Arms Range Studies

There have been several studies of sport shooting ranges world-wide but limited information is available for military SAR. Several investigations describe undesirable effects but when the data are applied to Camp Edwards, the results support conclusions previously presented, i.e. lead will not migrate significantly.

Much of the data in the technical literature is from sport ranges, where lead shot is used. Many similarities between military and sport ranges do exist with respect to both maximum lead concentrations and the use of shotguns for firing lead pellets (USACE 2006). However, many differences exist as well with the foremost being the size of the lead projectile as discussed in Section 1.4.3. An unfragmented M855, 5.56 mm projectile excluding the propellant casing is 22 mm long and 4 mm in diameter. In contrast, lead shot can range in diameter from 16 mm to less than 2 mm (Table 8). Most of the lead shot used on sport ranges is less than 2.4 mm in diameter, which is considerably smaller than the shot used on military ranges. Typically, the military uses 00 Buck shot, which has a diameter of 8.4 mm in diameter. The M-16 5.56 mm is designed not to fragment upon impact although fragmentation can occur (Fackler 2007, Larson *et al.* 2006) but the degree of fragmentation has not been quantified. Larson *et al.* (2006) work found the majority of the lead mass associated with the greater than 2 mm soil size fraction. Our own SAR work, unpublished, supports the Larson *et al.* (2006) findings in that most of the metal mass is concentrated in the > 2mm soil size fraction. Both of these studies looked at 25 m ranges. Fragmentation will be less at those ranges with greater distance to the target such as the Tango Range. Planned training at Camp Edwards is mostly with M-16 copper-jacketed bullets (some shotgun training will occur at the O Range and potentially other ranges), which is expected to result in less exposure to biota than the use of lead shot at sport ranges. The military typically uses single slugs or 00 Buck Shot and the later has a diameter four times larger

than the lead shot used on sport ranges. Due to the greater number of lead shot pellets in sport shot, the surface area is 2 to 3 times greater than that for 00 Buckshot.

Studies from other ranges show the greatest lead concentrations near impact sources (impact and lateral berms and shotfall zones). For example, soil samples from the backstop berms at four sport shooting ranges contained lead as high as 60,600 mg/kg (Cao et al. 2005). The highest concentration reported at Camp Edwards was at the Current G Range with more than 12,000 mg/kg (Table 4). Slightly elevated lead levels have also been found at firing lines (Table 5), because common military primer formulations (FA-956 and FA-70), igniters, and propellants include organo-lead compounds (lead thiocyanate, lead styphnate, lead stearate, and lead salicylate) at approximately 0.1 to 0.2 grams per bullet (MIDAS 2007). Lead carbonate also is added to inhibit corrosion of gun barrels. Cao et al. (2003a, 2003b) examined several rifle ranges in Florida with similar characteristics to Camp Edwards—the primary difference being temperature and depth to water. The conditions for lead mobility in Florida present a relatively more favorable lead-transforming environment because of the combination of high moisture and year-round elevated temperatures (Chen et al. 2002, Cao et al. 2003a). Little movement below the surface was found for the five ranges investigated, although most surface soils failed the TCLP (Cao et al. 2003b). The soil samples indicating low leaching potential and the areas where lead movement in shallow groundwater was limited had the highest soil phosphate levels. At only one site did a “substantial amount of lead migrate to the subsurface”. However, “subsurface” referred to the concentration of lead at 1 m and the quantity of lead present was a factor of 10 less than the surface concentration. An additional factor of 10 decrease after another meter of migration and the concentration would be at background.

At only one site reviewed, the Prime Hook National Wildlife Refuge in Delaware, was “groundwater contamination” described (Soeder and Miller 2003). At the Prime Hook site lead shot, 1 to 2 mm in size, was fired into a forested wetland area with acidic soil and surface water. Depth to the water table was generally less than 1 m with groundwater discharge into a stagnant slough. The surface water and groundwater had a high TOC content and the sandy quartz aquifer material lacked iron oxide coatings. In contrast, depth to groundwater at Camp Edwards is over 30 m, the soils have a low TOC content (see Section 2.4.1), and the quartz grain aquifer material have iron oxide coatings (Appendix B). While the depth to groundwater and predominant particle size are believed to be the most important issues, sediment composition and ground-water chemistry are sufficiently similar that lead adsorption properties at the two sites are likely to be very similar. Also, the much-higher DOC concentrations observed at the Delaware site relative to Camp Edwards may not be significant.

Landmeyer (1994) and Knechtenhofer *et al.* (2002) reported additional investigations with relevance to Camp Edwards. The former study, conducted at an Air Force Shooting range in

Table 8. Shot size diameter, effective range, count, and usage.

Shot Name	Shot Diam (in.)	Shot Diam (mm)	Maximum Range (yd)	Maximum Effective Range (yd)	Shot Count (1 oz.)[1]	Comment

#9	0.08	2.03	176		585	Typically recommended for skeet

South Carolina, once again had berm soils failing the TCLP, but lead migration to the shallow water table (< 3 m) was not observed. Knechtenhofer *et al.* (2002) evaluated a sport shooting

range much more acidic than Camp Edwards (pH 3). A contaminated soil profile was irrigated sufficiently for ponding to remain visible on the surface for twenty hours. The lead concentration was 80.9 mg/kg in the topsoil but by 40 cm in depth, the lead concentration approached background. In summary, these studies indicated:

- Lead accumulation in firing lines and target areas was common,
- Surface soil samples frequently exceeded regulatory action levels and many were hazardous based on the TCLP, and
- Subsurface migration was limited to no more than approximately 1 to 3 m.

Another relative study is the evaluation of the Lake Merced sporting range in San Francisco, California (Crosby and Overton 1990a, 1990b). This particular site shares similar soil characteristics to Camp Edwards, i.e. a sand, loamy sand, or sand loam with little organic layer development. Although later studies (SFPUC 2005) have suggested a potential leaching concern based on TCLP tests, previous and ongoing field studies show that elevated lead levels are concentrated in the top 0.6 m of the soil with no lead above background present deeper than 1.5 m.

Bricka *et al.* (1996a) studied three military SARs at Fort Benjamin Harrison in Indianapolis, Indiana and found no elevated lead beyond a depth of 0.9 m from the surface. The soil at this site had much higher clay content than Camp Edwards. Similar results were seen at two zeroing ranges located at an Army installation in Louisiana. Lead migration was limited to 1.2 m in a clay rich soil (Bricka *et al.* 1996b).

Apart from high soil concentrations, among the undesirable effects observed at sport shooting ranges (Cao *et al.* 2003a, 2003b), were elevated lead concentrations in surface water and in plants grown in shooting range soils (Murray *et al.* 1997). The highest lead concentration was found in plant roots, and it was positively correlated with soil ethylenediaminetetraacetic acid (EDTA)-extractable lead concentrations (Rooney *et al.* 1999). Mellor and McCartney (1994) reported reduced crop density of plants grown within a shot-fall zone at soil lead concentrations of approximately 1,500 to 10,500 mg/kg. Elevated lead levels in water were reported by Stansley *et al.* (1992) in an investigation of eight target shooting ranges in the US. They suggested the weathering of lead pellets resulted in elevated concentrations of water-borne lead (0.004 to 0.84 mg/L versus 0.007 mg/L at the control sites). At a trap and skeet range located in Westchester County, New York, surface water lead concentration ranged from 0.060 to 2.9 mg/L (USEPA 1994). Labare *et al.* (2004) at a trap and skeet range in Westchester, New York reported lead mobility into nearby streams and sediment. This range, however, was adjacent to a stream. These studies emphasize the importance of preventing surface water runoff and the maintenance of sub-optimal growing conditions at Camp Edwards.

4.0 Opportunties for Further Studies

Although lead has not contaminated the groundwater in any significant way, uncertainties remain in regards to lead fate-and-transport. If there is a desire by MAARNG and others to reduce the uncertainty in regards to lead fate and transport, during the development of pollution prevention plans, specific studies could be conducted to address these issues. These recommendations are presented purely for the purpose of furthering our collective knowledge in the area of lead fate and transport behavior, and are in no way intended to undermine the conclusions which have been presented. A significant amount of resources have been invested into this project and much of the time was spent gathering and reviewing relevant studies that have been completed/published on lead behavior. Using our collective lessons learned for this study, and in an effort to more efficiently and effectively apply resources, in the future, we recommend the following:

4.1 Field Studies

One of the key issues to establish is whether lead is going into solution at the SARs. Although pore-water data has been collected at B, C, and I Ranges, these ranges have been treated with the Maectite^{TM} – phosphate material. Therefore, it is unclear whether the lack of lead in the soil pore-water is a function of leads inherent fate and transport properties or the application of the Maectite^{TM}. Consequently, it would be useful to install lysimeters at untreated SARs such as the Former B and D Ranges to assess whether lead without the addition of phosphate is mobile. Our recommendation would be to install the lysimeters at the base of the berm. For each range to be studied two clusters of two lysimeters at depths of 0.6 and 1.5 m are recommended at a minimum. It is our understanding that IAGWSP intends to install several lysimeters at Former D Range to conduct such an evaluation.

Although soil profiles could be collected to ascertain the transport of lead, the concern with lead relates to its migration to groundwater. Therefore, our recommendation is to focus on the soil pore-water rather than soil. There are several concerns with the collection of soil profiles the foremost being the potential for cross-contamination during sampling in the sandy soil. Previous soil profile sampling efforts at Camp Edwards have resulted in occasional detection of lead with depth. Consequently, this makes interpretation of the transport of lead more difficult. In addition, the typical soil profile represents a point in space. Thus, the results from a single profile may not be representative of the SAR due heterogeneity issues. In contrast, a lysimeter installed at depth integrates water collected over a larger area, the area integrated being dependent on the depth of the lysimeter installation. Although profile samples could be collected using a multi-increment approach this is a time consuming process.

However, if profile samples are desired it is recommended that a slit trench approach be used to collect the samples or a coring device. With either approach, great care should be taken to prevent cross-contamination of the samples owing to the sandy nature of the soil. Our recommendation would be to collect soil samples on 25 cm intervals for the top 200 cm and then a final sample at 300 cm. Due to the heterogeneous distribution of metals in soil a multi-increment sample approach is recommended utilizing the combining of samples from at least a minimum of six different borings. Further, we recommend that the berm face be broken it three separate decision units, i.e. the area above the bullet pockets, bullet pocket and eroded area, and the trough at the base of the berm. If there are concerns about lead at the firing point then this should be included as a separate decision unit.

In addition, further work could be conducted to establish the background level of lead in surface soils, and soil pore-water. This would involve the collection of additional soil samples and the installation of additional lysimeters. Further effort could also be spent further scrutinizing the few lead detections in monitoring well samples to assess their validity.

Finally, further work could be conducted to establish the background level of lead in surface soils, and soil pore-water. This would involve the collection of additional soil samples and the installation of additional lysimeters. Further effort could also be spent further scrutinizing the few lead detections in monitoring well samples to assess their validity.

4.2 Laboratory Studies

One of the key variables controlling the rate of movement of lead is the corrosion rate of metallic lead and the susceptibility of the resulting lead oxides to dissolution. Dissolution drip experiments could be conducted using unweathered and weather projectiles to assess the dissolution rate. Although, the species of lead oxides on lead shot has been studied at some sites a similar study has not been conducted for larger lead military projectiles with copper jackets. The lead oxides formed for military munitions may be different from those species found associated with lead shot since the composition of lead shot is different from that for military ammunition. Also, corrosion processes for copper jacketed lead projectiles may be different from lead shot. In addition, the site-specific geochemical environment at Camp Edwards may result in the formation of lead oxides different from other studies. Since the lead oxides are the species most likely dissolved knowing the form present would allow proper selection of the lead solubility value used in transport modeling. The current modeling approach is to select a conservative solubility value, which may lead to higher predicted lead groundwater values than warranted. In turn, this approach may lead to conservative soil action levels.

Another key unknown is the affinity of the dissolved species of lead to the soil matrix. This could be assessed through batch or column K_d experiments using site specific SAR soils. Presently,

only a single site-specific K_d value (34 mL/g) is available for Camp Edwards and this sample was obtained from the Impact Area. Many of the modeling lead assessments conducted by the USEPA have used a default K_d value of 900 mL/g with the literature suggesting even higher values. USEPA (2005) suggests that K_d values can range over several orders of magnitude for samples collected from the site. Given the importance of K_d in the transport models, i.e. it is the key controlling variable determining the depth of migration, collection of half dozen samples would seem prudent. These batch experiments should then be confirmed with several column studies since batch experiments tend to under predict sorption kinetics.

5.0 Conclusions

This report has assessed the fate of lead released into the environment at Camp Edwards from firing at small arms ranges. The principal conclusions are corrosion, dissolution processes are sufficiently slow, and mechanisms for attenuation, such as precipitation and adsorption, sufficiently robust, that lead has not migrated to groundwater. This review also indicates quantification of soil sorptive capacity cannot be accomplished in any meaningful way. These conclusions are supported by the following facts:

1. Multiple soil profile samples collected prior and post berm-maintenance from six small arms ranges indicated little vertical migration of lead,

2. Geochemical conditions within the surface soils, (e.g. pH, chloride, resistivity, permeability, and oxygen) are not conducive for significant corrosion, dissolution, and transport of lead,

3. Experimental results from other studies with conditions similar to Camp Edwards showed minimal lead movement,

4. Experimental results from other studies consistently demonstrate such high and variable measurements for lead partition coefficients that modeling exercises typically have uncertainties on the order of centuries in their predictions,

5. Geochemical studies found in literature suggest the propensity to form insoluble precipitates, and not sorptive capacity, may be the most important factor controlling lead migration in the subsurface,

6. The corrosion/dissolution rate, although qualitatively predicted to be slow, cannot be quantified because of several uncertainties ranging from uncertainty regarding the particle size distribution to the effects of wet/dry cycles,

7. Unsaturated zone modeling using two different software codes predicted the vertical migration of lead would take centuries to reach groundwater,

8. Water samples from most monitoring wells (except MW-72S) installed immediately downgradient of the backstop berms at a number of small arms ranges showed no measurable lead,

9. Groundwater data collected to date from across Camp Edwards demonstrated little to no lead contamination as a result of accumulation from small arms training, despite lead being continuously released to soil for more than 60 years,

10. Tracer studies conducted by the USGS near MMR demonstrated an aqueous form of lead was rapidly adsorbed onto the soil, implying the same reactions will attenuate lead movement in the unsaturated zone, and

11. Lead introduced into the groundwater at MMR in a sewage treatment effluent was quickly and completely attenuated.

The technical literature, however, clearly describes dangers to humans and wildlife exposed to lead. Although lead mobility is limited in the Camp Edwards environment, there is not adequate data to date to quantify the amount of lead that can be safely deposited in the environment. It is important, therefore, to minimize environmental exposure through the application of best management practices.

Appendix A

SOLUBILITY PRODUCT CONSTANTS OF LEAD MINERALS AND COMPOUNDS

Table A-1 lists the lead compounds or minerals mentioned in the main text as well as some other minerals for which data were found. The latter are included for comparison purposes. An attempt was made to find the solubility product constants for each mineral in the table but some were not readily available.

This literature search was extensive but not exhaustive, therefore, additional data may be available. Furthermore, it is emphasized that these measurements are typically difficult to perform and are affected by pH, temperature, presence of competing ions and many other factors. In some cases, there is controversy regarding the precise mineral formula as with lead pyromorphites where 4 lead molecules and not 5 are sometimes included in the formula. Hence, direct application of these values to solubility in the field usually requires site-specific research.

Typically, the data in the Table are for room temperature (20-25^{o}C) and deionized water. The majority of the data are from Traina et al. (1999) and from sources cited in the main text.

In considering those compounds where data are not available, note that the main text quoted the following: Common lead minerals which form in most soils decrease in the order of solubility as follows: PbO > $PbCO_3$ > $Pb_3(CO_3)_2(OH)_2$ > $PbSO_4$ > $PbHPO_4$ > $Pb_5(PO_4)_3OH$ > $Pb_5(PO_4)_3Cl$ (Lindsay 1979).

Table A-1. Solubility products of selected Pb minerals.[1]

Mineral	Formula	Log K_{sp}*
Litharge	**PbO**	**12.9**
Massicot[2]	**PbO**	**?**
Anglesite (lead sulfate)	**$PbSO_4$**	**−7.7**
Cerussite	**$PbCO_3$**	**−12.8**
Hydrocerrusite	**$Pb_3(CO_3)_2(OH)_2$**	**?**
Lead (Hydr)oxide	**$Pb(OH)_2$**	**-14.9**
Lead Hydroxyapatite	**$Pb_5(PO_4)_3(OH)$**	**?**
Galena	**PbS**	**-27.6**
Lead Phosphate	**$Pb_3(PO_4)_2$**	**-54**
Lead Oxyphosphate	**$Pb_4O(PO_4)_2$**	**?**
Pyromorphite	**$Pb_5(PO_4)_3Cl$**	**−84.4**
Hydroxypyromorphite	**$Pb_5(PO_4)_3OH$**	**−76.8**
Plumbogummite	**$PbAl_3(PO_4)_2(OH)_5 \cdot H_2O$**	**−99.3**
Fluoropyromorphite	$Pb_5(PO_4)_3F$	−71.6
Bromopyromorphite	$Pb_5(PO_4)_3Br$	−78.1
Corkite	$PbFe_3(PO_4)(SO_4)(OH)_6$	−112.6

Hindsalite	$PbAl_3(PO_4)(SO_4)(OH)_6$	−99.1
Lead-bearing Jarosites	**$KFe_xPb_x(SO_4)_2(OH)_6$**	**?**

[1]Minerals or compounds in bold print are mentioned in the report.

[2]Massicot and Litharge have the same formula but different crystalline structure.

Milford, MA 01757

Dear Mr. Cody:

At your request, Dr. Douglas Kent has prepared the attached summary of research by the U.S. Geological Survey on the fate and transport of metal ions in ground water in the aquifer of western Cape Cod. The research was done under the auspices of the USGS Toxic Substances Hydrology Program. The summary focuses on findings of particular relevance to the potential for migration of lead in the subsurface.

We hope the findings of the USGS research are helpful in your assessment of the fate of lead at the small-arms ranges at Camp Edwards. Please don't hesitate to contact Dr. Kent or me if you have any questions about the summary or the USGS research program on Cape Cod.

Sincerely yours,

Denis R. LeBlanc
Hydrologist

LEAD ADSORPTION AND TRANSPORT STUDIES CONDUCTED AT THE U. S. GEOLOGICAL SURVEY TOXIC SUBSTANCES HYDROLOGY RESEARCH SITE ON CAPE COD, MASSACHUSETTS

Prepared for the Massachusetts National Guard
Environmental & Readiness Center
Massachusetts Military Reservation

By Douglas B. Kent and Denis R. LeBlanc
U. S. Geological Survey

December 5, 2006

Draft. Not for Citation

Introduction and Background

Since 1983, U. S. Geological Survey (USGS) scientists and their colleagues from universities and other research institutions have conducted research on processes controlling the fate and transport of contaminants of national and global concern at a site on western Cape Cod (USGS research site). The site is located downgradient of the Massachusetts Military Reservation (MMR) wastewater-treatment facility, where a 60-year period of discharge of wastewater, which ended in 1995, resulted in a plume of wastewater-contaminated ground water. Research at the site is conducted under the auspices of the USGS Toxic Substances Hydrology Program. Multi-disciplinary research involving long-term field studies, field-scale transport experiments, laboratory experiments, and computer modeling has focused on identifying critical processes influencing the transport of pathogens, nutrients, organic, and inorganic contaminants (LeBlanc, 2006). The purpose of this report is to summarize principal findings from these studies that are relevant to understanding the potential mobility of lead(II) (Pb^{2+}) in the aquifer on western Cape Cod.

The shallow aquifer on western Cape Cod is developed in non-calcareous sediments and, therefore, ground water is mildly acidic with low concentrations of dissolved carbonate and other dissolved salts. Under these chemical conditions, Pb-containing solids (including hydroxides, carbonates, and sulfates) are undersaturated at Pb concentrations below approximately 26 milligrams per liter (mg/L) (which equals 125 micromoles per liter, µM). Thus, mineral solubility reactions will not limit Pb

concentrations until they exceed this value. Under these conditions, Pb concentrations and mobility will be controlled by adsorption. Adsorption results from reactions between aqueous species and sites at sediment surfaces. A considerable amount of work has been published by USGS researchers and their colleagues on the adsorption properties of the sediments, the transport of adsorbing metal ions and other inorganic solutes, and reactive-transport modeling of the fate and transport of adsorbing solutes in the aquifer. The best studied metal cation is zinc(II) (Zn), but adsorption of Pb has also been described, as has been the transport of Pb complexed with the strong complexing agent ethylenediaminetetraacetic acid (EDTA). Other adsorbing solutes whose adsorption and transport have been investigated include molybdate, phosphate, arsenate, arsenite, chromate, selenate, nickel(II) (Ni), and copper(II) (Cu).

Adsorption Properties of the Sediments

The mineralogy and adsorption properties of the sediments collected from the USGS research site have been studied extensively. The sediments are comprised of greater than 90 percent quartz with minor quantities of feldspars and accessory ferro- and aluminosilicates and oxides (Barber 1990; LeBlanc and others, 1991; Davis and others, 1993; Coston and others, 1995). Although quartz is the most abundant mineral, adsorption properties of the sediments are dominated by coatings on quartz grains that are comprised primarily of aluminum (Al), iron (Fe), and silicon (Barber and others, 1992; Coston and others, 1995; Fuller and others, 1996; Davis and others, 1998). Hematite particles on the order of 5 nanometers in diameter have been identified in the coatings along with aluminosilicates and oxides too poorly ordered to be identified mineralogically (Banfield and Hamers 1997). Adsorption studies have shown that, on a per unit surface area basis, the sediments adsorb cations more strongly and anions more weakly than hydrous ferric oxide (Stollenwerk, 1995; Kent and others, 1995, 2002; Davis and others, 1998). Clay minerals have not been identified in bulk sediment samples but kaolinite and, possibly, smectite and chlorite have been identified in material isolated from interiors of feldspar grains, where they are likely forming as alteration products (Wood and others, 1990; Bau and others, 2004).

Laboratory experimental studies have shown that Pb adsorbs extensively on sediments collected at the USGS research site. The extent of Pb adsorption increases with increasing pH. At a total Pb concentration of 10 µM (2.1 mg/L) and a surface-area-to-volume ratio of 22 square meters per liter (m^2/L) (which corresponds to a solid-liquid ratio of 50 grams per liter), the percentage of Pb that was adsorbed onto the sediments increased from approximately 25 percent at pH 4 to 100 percent at pH 6.5. Zinc also adsorbs extensively on the sediments, but Pb adsorption is much more extensive (Coston and others, 1995; Fuller and others, 1996).

Fuller and others (1996) examined factors controlling spatial variability in Pb adsorption by sediments at the USGS research site. At constant solution conditions and solid-liquid ratio, the concentration of Pb adsorbed onto 374 different sediment samples varied by less than a factor of 4, with values for most samples falling within a factor of 2.

Lead adsorption correlated well with the crystalline Fe-plus-Al-oxide content of the sediment-coating materials when the adsorbed Pb concentration and the Fe-plus-Al-oxide content were normalized to specific surface area. The crystalline Fe-plus-Al-oxide content was determined using a citrate-dithionate extraction. No significant correlation between adsorbed Pb concentration and hydraulic conductivity of the sediments (estimated from grain-size distribution) was observed.

Mobility of Lead and Other Strongly Adsorbing Metal Ions

Adsorption of Pb, Cu, and Zn on the sediments over the range of ground-water chemical conditions observed at the USGS research site can be well described by reactions of the form:

$$Me^{2+} + >S_sOH = >S_sOMe^{+} + H^{+}$$
$$Me^{2+} + >S_wOH = >S_wOMe^{+} + H^{+}$$

where Me^{2+} represents the metal ion (Pb, Cu, or Zn) and $>S_sOH$ and $>S_wOH$ represent adsorption sites with different binding strengths (Davis and others, 1993, 1998; Fuller and others, 1996). A model of this form calibrated using laboratory data for Zn adsorption on sediments from the site predicted the large impact of variable pH on the mobility of wastewater-derived Zn in the aquifer (Kent and others, 2000).

Field experiments have been conducted at the USGS research site in which Pb and other metal ions complexed with EDTA were injected into the aquifer. In one experiment, 600 liters of ground water with 100 µM each of Pb, Ni, Cu, and Zn as EDTA complexes were injected into the aquifer (Podey and Lewandowski, 1997). A concentration of 100 µM corresponds to 20.7 mg/L Pb, 5.9 mg/L Ni, 6.4 mg/L Cu, and 6.5 mg/L Zn. Breakthrough curves for all four metal ions, collected 2.5 meters downgradient from the injection well, are shown in figure 1. Concentrations were normalized by dividing the concentration of each metal determined at any given time by its concentration in the injectate solution. For all four metal ions, only the EDTA complexes were detected; concentrations of free metal ions (concentrations for metal ions not complexed with EDTA) could not be detected. Concentrations of Cu and Zn were below those of Ni in most samples. Concentrations of Pb were much lower than concentrations of Ni in all samples. Normalized concentrations of Ni were equal to normalized concentrations of bromide, which was the conservative, non-reactive solute added to trace the movement of the injected water. This shows that there was no loss of Ni from the tracer cloud over the 2.5-meter transport distance (Kent and others, 2002). In contrast, the fact that concentrations of Cu, Zn, and Pb were lower than the corresponding concentration of Ni is evidence of a loss of these metals to the sediments over the 2.5-meter transport distance. Integration under the breakthrough curves shows that almost 40 percent of the injected Pb was lost from the tracer cloud over the 2.5-meter transport distance. Concentrations of Fe-EDTA complexes accounted for all of the EDTA that was not complexed with Ni, Cu, Zn, or Pb.

The observed loss of metal ions from EDTA complexes occurs as a result of the following reaction:

$$MeEDTA^{2-} + Fe(OH)_{3,s} + >SOH + 2H^{+} = >SOMe^{+} + FeEDTA^{-} + 2H_2O$$

Metal ions complexed with EDTA are displaced by iron(III) (Fe(III)) leached from the sediments. The free metal ion displaced from EDTA complexes (Me) adsorbs to the sediments (Davis and others, 2000; Kent and others, 2002). The thermodynamic driving force for the reaction stems from the strength of the metal-ion-EDTA complexes and the strength of binding of the free metal ion to sediment surface-sites. Equilibrium constants for the formation of metal-EDTA complexes decrease in the order:

Ni~Cu>Pb>>Zn

Equilibrium constants for adsorption of metal ions to the sediments, as determined in laboratory experiments, decrease in the order:

Pb>>Cu>>Zn>Ni.

Overall, one predicts that the extent to which these metals would be displaced should decrease in the order (Davis and others, 2000):

Pb>>Zn~Cu>>Ni.

This order of displacement agrees with that observed experimentally (fig. 1). The extent to which the displacement reaction occurs during transport is limited by the slow rate of dissolution of Fe(III) from the sediments (Friedly and others, 2002).

In another experiment, 10,000 liters of ground water with 250 µM PbEDTA (which equals 52 mg/L Pb) were injected into the aquifer and transport was monitored over approximately one year (Davis and others, 2000). Concentrations of Pb decreased rapidly during the experiment. Approximately 100 days after the injection, during which time the center of mass of the tracers had moved approximately 40 meters, Pb concentrations in the tracer cloud had decreased to below detection.

Survey of Dissolved Lead and Other Metal-Ions Concentrations near the Abandoned MMR Wastewater-Infiltration Beds

In order to examine further the potential for significant concentrations of Pb to occur in the aquifer, ground water in the vicinity of the abandoned infiltration beds at the MMR wastewater-treatment facility was sampled in 2006. The beds were last used in December 1995. Wastewater from the treatment facility contained low concentrations of Pb, along with other metal ions, such as Zn and Cu, that are typically associated with pipe corrosion. Concentrations of Pb in wastewater discharged to the disposal beds at the MMR were in the range of 6-29 µg/L (0.03-0.14 µM) (E. C. Jordan, 1986; Vaccaro and

others, 1979). Concentrations of Cu and Zn were 40-90 µg/L (0.6-1.4 µM) and 25-130 µg/L (0.4-2.0 µM), respectively (E. C. Jordan, 1986; Vaccaro and others, 1979). More recent assays of the wastewater discharged to the beds found similar concentrations of Cu and Zn, but the analytical methods used were not sufficiently sensitive to determine Pb concentrations at the low levels previously observed in the wastewater (Rea and others, 1991, 1996; Savoie and LeBlanc, 1998; Kent and others, 2000).

Sampling locations were chosen at which wastewater-derived Zn and Cu had been detected consistently over the past decade (Kent and Maeder, 1999; Kent and others, 2000). The sampling locations are shown in figure 2 and the sampling-site characteristics are given in table 1. Samples were collected, filtered, and preserved by acidification as described elsewhere (Savoie and LeBlanc, 1998). Concentrations of Pb, Cu, Zn, and other inorganic solutes were determined by inductively coupled plasma mass spectrometry. The limit of quantitation for Pb was 0.08 µg/L (0.0004 µM); the limit of quantitation for Cu and Zn was about 0.4 µg/L (0.006 µM).

Concentrations of dissolved Pb, Cu, and Zn, along with other water-quality data are presented in tables 2-4. Concentrations of Pb were at or below the limit of quantitation in all samples. In contrast, dissolved Zn and Cu were detected in most samples. Dissolved Zn and Cu concentrations in shallow ground water under the wastewater-disposal beds (for example, samples at MA SDW 473-M01-02GNT, MA SDW 436-M01-02GNT, and MA SDW 469-M01-02GNT) were in the same range as those previously determined in the wastewater samples themselves. Concentrations of Zn and Cu were similar to those observed at these sampling points over the past several years (Kent and Maeder, 1999).

Conclusions

Results of experimental studies and determinations of metal-ion concentrations in the wastewater-contaminated ground water at the USGS research site on Cape Cod have implications for assessing Pb concentrations and mobility in the aquifer. First, Pb adsorbs extensively on the sediments. Extensive adsorption should help maintain low concentrations and mobility of Pb in the aquifer. Assuming that Pb concentrations in the wastewater discharged to disposal beds at the MMR wastewater-treatment facility were consistently in the range 1-10 µg/L over the 60 years during which disposal to these beds occurred, the observed absence of Pb at concentrations above 0.08 µg/L in shallow ground water below the beds must be a result of extensive Pb adsorption onto the sediments. Second, laboratory experimental studies have shown that adsorption of Pb onto the sediments is a strong function of pH, with Pb adsorption decreasing with decreasing pH. Thus, the mobility of Pb should be greater at lower pH values, as has been previously shown for Zn (Kent and others, 2000). Third, at a pH of 5.8, which is a typical pH value in uncontaminated ground water at the USGS research site, adsorption of Pb onto the sediments should be extensive and Pb concentrations in equilibrium with the sediments should be very low. Twenty-one grams of Pb complexed with EDTA at a concentration of approximately 52 mg/L (250 µM) was completely removed from ground water injected into the aquifer at pH values at or near 5.8 by adsorption onto the

sediments over a transport distance on the order of 50 meters. Fourth, if a region of the aquifer were to become contaminated with Pb, a subsequent decrease in pH values in that region would be expected to result in increases in concentrations and mobility of Pb in that region. This has been observed for Zn and has been shown to result from the pH-dependence of metal-ion adsorption on the sediments (Kent and others, 2000).

Groundwater Letter Report
Phase 1 and Phase II Tungsten
Small Arms Range Study

Massachusetts Military Reservation

Jay L. Clausen
Environmental Sciences Branch
Physical Research Scientist
Us Army Corps of Engineers
Engineer Research & Development Center
Cold Regions Research Engineering Laboratory
72 Lyme Road

BACKGROUND

This Letter Report covers both phases (I and II) of the US Army Environmental Command managed Tungsten Small Arms Range (SAR) Study and includes all water data generated as part of this study. Soils data can be found in other previously released reports (Clausen et al. 2007). Also included in this report are some data generated by the Impact Groundwater Study Program (IAGWSP) for comparison purposes.

The US Army Corps of Engineers, Environmental Research and Development Center, Cold Regions Research Engineering Laboratory (ERDC-CRREL) of Hanover, NH was tasked by the US Army Environmental Command (USAEC) to assess the fate-and-transport properties of tungsten leaching from tungsten/nylon bullets. Camp Edwards at the Massachusetts Military Reservation (MMR) was chosen as the first study site because tungsten/nylon projectiles have been fired there since October 1999 and detailed records were available for the number of bullets fired per range. There are 20 small arms firing ranges at Camp Edwards, and tungsten/nylon projectiles were fired at 12. The greatest numbers of tungsten projectiles were fired on Bravo (B), Charlie (C), Known Distance (KD), Southeast (SE), Southwest (SW), Golf (G), and India (I) Ranges. Given the similarity of the soil and meteorological conditions across the Camp Edwards installation, the major factor in selecting B, C, and I Ranges was the number of tungsten rounds fired and the presence of a berm behind the targets.

In Phase I, ERDC-CRREL 1) mapped the distribution of tungsten in the surface soils and sub-surface locations at B, C and I Ranges, 2) installed shallow pore-water lysimeters under and near the impact berms B, C and I Ranges, and 3) sampled four pre-existing IAGWSP groundwater monitoring wells (MW-72S, MW123S, MW-135M2, and MW-404S) (Appendix A).

The IAGWSP, in the meantime, installed and sampled 12 new groundwater monitoring wells (Appendix A) located near small arms ranges and their contract laboratory, Severn Trent Laboratories (STL) in Colchester, Vermont, found low-level tungsten concentrations (1 to 4 µg/L). While not part of our study, the IAGWSP STL results are summarized in this letter report for the convenience of the reader. Additionally, the IAGWSP wanted to know if the tungsten observed by STL was due to training with tungsten/nylon ammunition or represented background levels. To help answer their question 12 pre-existing IAGWSP monitoring wells were sampled (Appendix A) and analyzed by Northern Arizona University (NAU) of Flagstaff, AZ to measure tungsten background levels as part of the Tungsten SAR Study Phase II activities. NAU is a secondary confirmation lab under contract to ERDC-CRREL.

In addition, as part of the Tungsten SAR Phase II activities three deep lysimeters, eight drive points, and eight additional groundwater monitoring wells (Appendix A) were installed with the goal of mapping the extent of tungsten in the aquifer near the B, C, and I small arms ranges at Camp Edwards. The location for these sampling devices was based on the results from Tungsten SAR Phase I Study. This letter report focuses

on the Phase II results for the deep lysimeters, drive-points, and monitoring wells and summarizes Tungsten SAR Study Phase I groundwater results.

INTRODUCTION

Firing a tungsten/nylon bullet introduces tungsten and other projectile-related metals (e.g. copper) into the environment. Most projectiles have stable flight paths and impact the berm behind the targets forming depressions called bullet pockets. During Phase I we found the highest soil tungsten levels in the bullet pockets, between the bullet pockets and in the trough at the base of the berm (Clausen et al. 2007). Soil concentrations generally correlated with the number of rounds fired. The concentration of tungsten in subsurface soils (generally less than 1 mg/kg) is significantly lower than surface soils and decreases with depth. Soil pore-water in the unsaturated zone beneath the bullet pockets and trough areas has tungsten at levels that correlate with the surface soil concentrations (Clausen et al. 2007). Relatively high levels of tungsten (up to 400 mg/L in the unsaturated zone pore-water at depths up to 65 cm) indicates tungsten is mobile through these sandy, acidic, aerobic soils. The mean tungsten concentration for lysimeters installed in background locations is 0.09 mg/L and ranged between 0.011 to 0.169 mg/L.

SUMMARY OF TUNGSTEN SAR STUDY PHASE I GROUNDWATER RESULTS

Water was sampled four times for tungsten from four monitoring wells, two near small arms ranges (MW-72S and MW-123S) and two background wells (MW-135M2 and MW-404S). Tungsten was found in monitoring well MW-72S, located on the B Range floor, approximately 10 m downgradient of the impact berm. At MW-72S, the samples from the first two events of 12/15/05 and 2/8/06, yielded tungsten concentrations of 15 and 25 µg/L, respectively (Table 1). The third sample event on 5/10/06 had a tungsten concentration of 560 µg/L and later samples on 6/21/06 had less than 6 µg/L (Table 1). Firing of the tungsten round was discontinued in February 2006 and soil containing greater than 150 mg/kg tungsten was removed in May (the soil removal activity spanned several weeks) from the berms at B, C, and I Ranges as well as others in between the 5/10/06 and 6/21/06 groundwater sampling dates.

The other downgradient well, MW-123S had no tungsten above the reporting limit of 1 µg/L (Clausen et al. 2007). MW-135M2 and MW-404S were background wells located where tungsten bullets had not been fired. These background samples had tungsten levels below 1 µg/L, the reporting limit. Two independent laboratories, US Army Corps of Engineers, Engineering Research and Development Center, Environmental Laboratory (ERDC-EL) of Vicksburg, MS and NAU, analyzed these water samples. Both laboratories reported similar tungsten concentrations for all water samples, i.e. monitoring wells and lysimeters (Clausen et al. 2007).

Table 1. Summary of tungsten results for MW-72S located on Bravo Range and MW-123S located downgradient between Bravo and Charlie Ranges.

SUMMARY OF TUNGSTEN SAR STUDY PHASE I LYSIMETER RESULTS

Table 2 is a summary of the lysimeter tungsten results obtained during Phase I of the Tungsten SAR study and provided in (Clausen et al. 2007). Tungsten levels as high as 400 mg/L were obtained in the lysimeters installed beneath the berm face. As reported earlier, some of these shallow lysimeters indicated an increasing tungsten concentration trend, some indicated a decrease in concentration through time, and others no trend. Background levels of tungsten were measured and were generally less than 0.2 mg/L.

Table 2. Shallow lysimeter Phase I tungsten results (mg/L).

METHODS

All of the water samples from the monitoring wells were collected in 500 ml plastic bottles by ECC, a contractor working for the US Army Corps of Engineers – New England District (CENAE) on behalf of the IAGWSP. In general, four samples were collected from each well; 1) unfiltered and unpreserved, 2) unfiltered and preserved, 3)

filtered and unpreserved, and 4) filtered and preserved. Samples were filtered in the field using an in-line 0.45µm filter. Preserved samples were collected in pre-acidified sample bottles containing nitric acid. All samples were then chilled to 4^{o}C and shipped to Severn Trent Laboratory (STL) in Colchester, Vermont who is the IAGWSP contract laboratory. In several cases sample splits were provided to ERDC-EL and NAU either as part of the Phase II Tungsten SAR Study or as a service under a separate contract to the US Army Corps of Engineers - New England District (CENAE) in support of the IAGWSP. Drive-point samples and lysimeter samples for our study were collected unacidified according to our procedures for tungsten (Clausen et al. 2007).

Tungsten was determined at ERDC-EL and NAU using inductively coupled plasma mass spectrometry (ICPMS) following EPA Method 6020, with samples prepared following EPA Method 3050 with some modifications (Clausen et a. 2007). Method 3050 typically involves preserving the water sample by adding a small volume of acid. However, acidification can influence tungsten solubility and speciation. Using concentrated acid is especially problematic when determining tungsten because acids can form insoluble tungstates and polytungstates. Therefore, ERDC's procedure for tungsten analysis calls for no field preservation with acid. The samples were simply chilled to 4^{o}C. For those samples not preserved upon collection both NAU and ERDC-EL acidify the sample aliquot with nitric acid immediately prior to injection into the ICP/MS. This acidification stabilizes the other metals present and allows for their analysis. The short contact time between any tungsten in solution is insufficient for any insoluble tungstates and polytungstates to form.

During Phase I of the Tungsten SAR Study, many of the lysimeter and monitoring well samples were split and sent both to ERDC-EL and NAU for analysis. Our analysis of the data as reported in Clausen et al. (2007) demonstrated good agreement between these two independent laboratories. Consequently, we have a high degree of confidence in reporting tungsten levels down to 1 µg/L.

As indicated earlier, the IAGWSP collected both acidified and unacidified for their program. It is believed that STL generally followed similar sample preparation and analytical procedures. Although, it is our understanding that in late 2006 STL was not acidifying the unpreserved samples immediately prior to instrument injection with nitric acid. Sometime later on it is believed STL adopted ERDC's approach of acidifying the unpreserved samples immediately prior to instrument injection. The exact details are available from CENAE/IAGWSP. As will be discussed later, inconsistent tungsten results are apparent between ERDC-EL and STL, principally for those STL samples analyzed in 2006. In most cases the issue involves a reported tungsten detection by STL and no detection by ERDC-EL. The CENAU conducted a round-robin study to evaluate this issue and information from this evaluation is available from the CENAE/IAGWSP.

The reporting limit for tungsten ranges from, 1-15 µg/L with a detection limit of approximately 0.2 µg/L for STL and 0.3 to 0.8 µg/L for ERDC-EL and NAU. The detection and reporting limits vary from sample run to sample run due to differences in

calibration as well as matrix interferences. In addition to tungsten, ERDC-EL analyzed for antimony, arsenic, chromium, copper, iron, lead, manganese, molybdenum, nickel, selenium, vanadium, and zinc. For complete details on analysis and preparations performed by NAU and ERDC-EL, see Clausen et al. (2007).

RESULTS

Tungsten Background levels

The locations for the wells used to determine the background tungsten concentration in groundwater were selected by ECC, a subcontractor to the CENAE. Groundwater samples were collected from April 3 to April 26, 2007 by ECC. Samples were sent to STL for the IAGWSP with splits provided to NAU as part of the Tungsten SAR Study. Their location is shown in Figure 1 and pertinent information on each well is given in Table 3. Background concentrations for the 12 monitoring wells, shown in Figure 1, are below NAU's detection limit of 0.5 µg/L and below the reporting limit of 1 µg/L (Table 4). STL's detection limit is 0.2 µg/L. The STL data is provided in Table 4 as a point of comparison. Both the NAU and STL found no detectable tungsten in the background well samples (Table 4).

NA – not analyzed by NAU

Phase II Water Sampling

Results from Phase I showed that tungsten had migrated to the aquifer in less than 6 years based on data from well MW-72S on B Range (Clausen et al. 2007). Therefore, in Phase II an objective was to determine how tungsten was migrating from surface soil to groundwater and assess the extent of transport in the aquifer. Three deep lysimeters, eight drive-points (temporary sampling points obtained with a Hyropunch type sampler), and eight groundwater wells were installed to map the extent of tungsten at B, C, and SE/SW Ranges. The locations of the drive-points and wells on B Range were based on the results from MW-72S and included input from CENAU, IAGWSP, and the regulatory agencies. Three deep lysimeters were installed at B Range as well as three drive points at B Range and five at Southeast/Southwest (SE/SW) Ranges (Table 5 and Figures 2 and 3). In addition, six monitoring wells were installed; two at B Range, one at Charlie (C) Range, and three at SE/SW Ranges.

Table 5. Location and number of lysimeters, drive-points, and monitoring wells installed as part of the Phase II Tungsten SAR Study.

Ranges	Bravo	Charlie	SE/SW	Total
Deep Lysimeters	3	0	0	3
Drive-Points	3	0	5	8
Monitoring Wells	3	2	3	8

Lysimeters

During Phase I, firing of tungsten nylon rounds was discontinued and berm soils containing > 150 mg/kg tungsten have been removed by the Massachusetts Army National Guard (MAARNG). Three deep lysimeters were installed beneath the former lower berm at B Range to assess the unsaturated zone transport rate of tungsten as part of Phase II of the Tungsten Study. To install the lysimeters the CENAE contractor used a high torque auger rig to drill the holes near the center of the range and near MW-72S, to a depth of 1.5, 4.6, and 7.2 m (5 ft (Lysimeter #30), 15 ft (Lysimeter #31), and 25 ft (Lysimeter #32). The lysimeters were spaced approximately 1-m apart. Lysimeter depths were selected to be between 0 and 10 m, the limit of peristaltic pump. The lysimeters were installed and sampled by ERDC-CRREL personnel using the same methods previously described in Clausen et al. (2007) and analyzed by ERDC-EL.

The lysimeters have been sampled six times and analyzed by ERDC-EL as part of the Tungsten SAR Phase II activities (Table 6). Tungsten levels are highest in Lysimeter #30, which is the shallowest lysimeter. In Lysimeter #31, intermediate depth, tungsten levels are consistently less than 5 µg/L. The tungsten results for Lysimeter #32 show a declining trend through time for the three samples recovered. Complete metal and field parameter results for the deep lysimeters are listed in Appendix B.

Figure 2. Location of drive-points and monitoring wells at Bravo and Charlie Ranges.

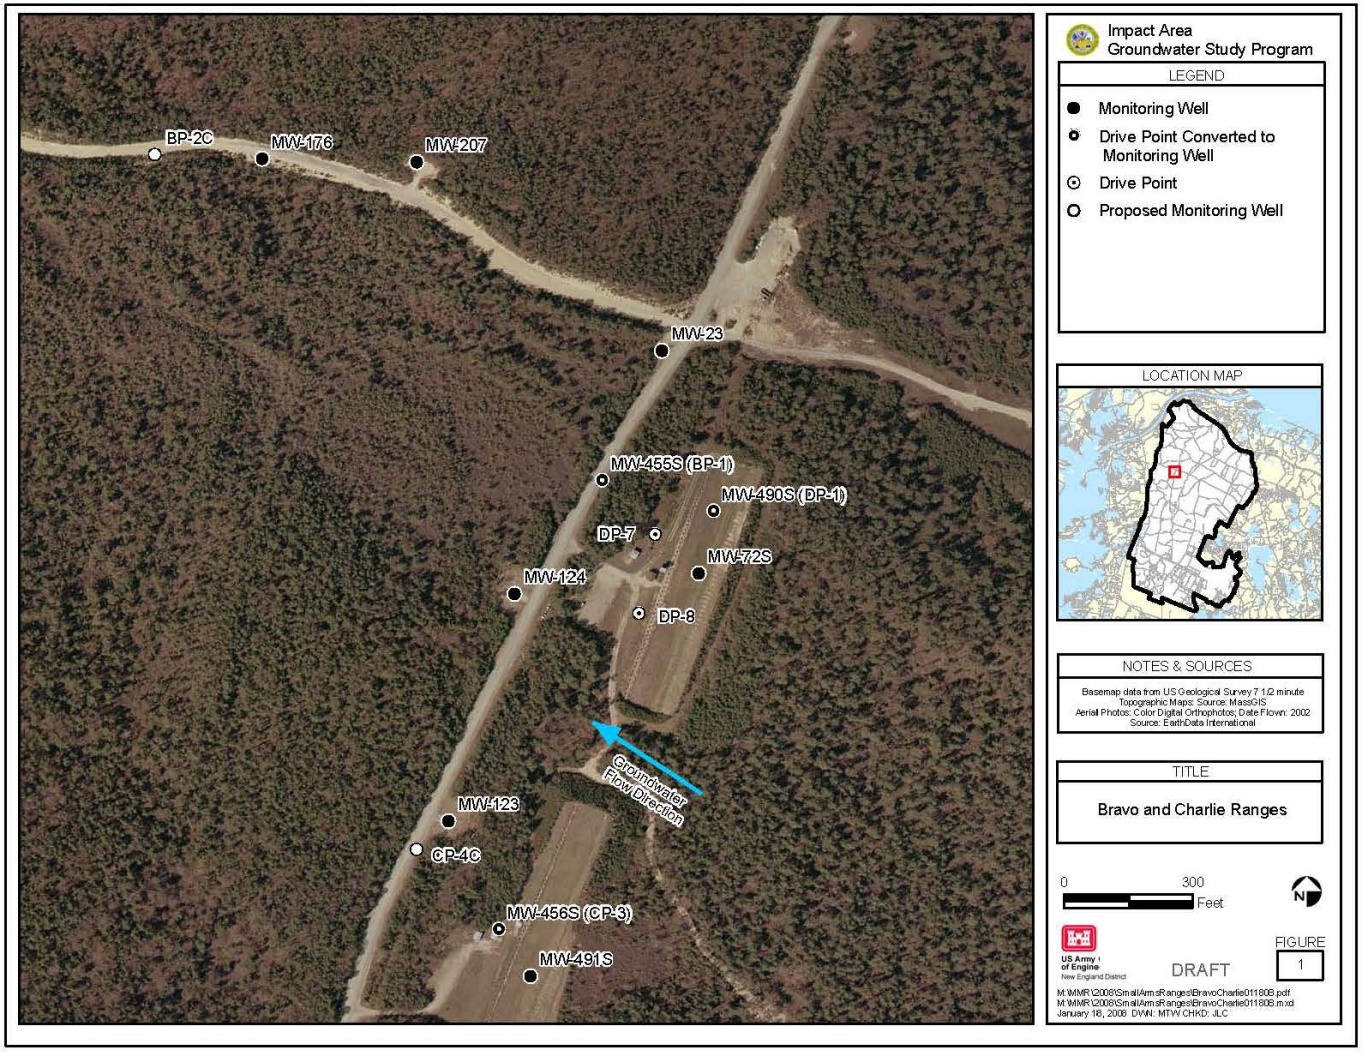

Figure 3. Location of drive-points and monitoring wells at Southeast/Southwest Ranges.

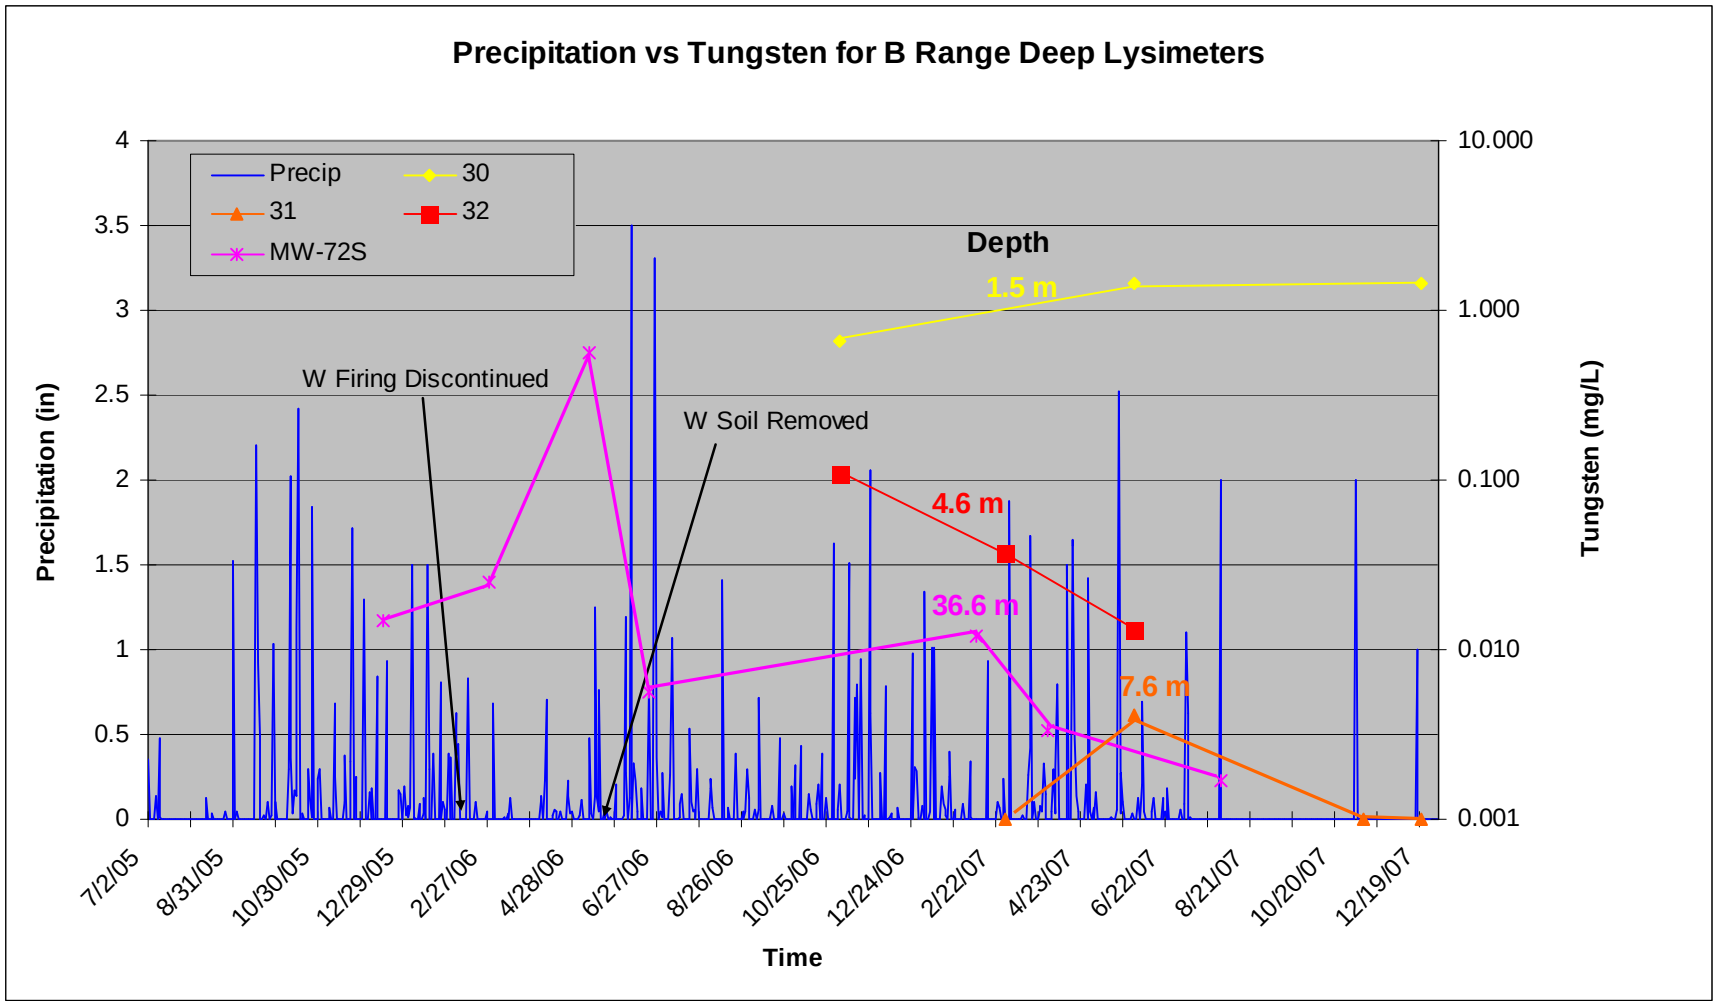
32	25	108	37	13	NW	NW	NW

NW – no water

Figure 4 plots the precipitation record for Camp Edwards and superimposes the tungsten concentrations from the lysimeters and MW-72S at B Range. The infrequent collection of lysimeter and well samples from Phase I and Phase II makes it difficult to determine if rainfall volume affects the tungsten concentrations in the water samples (Figure 4). No cause and effect relationship is evident between precipitation levels and groundwater tungsten concentration levels even when taking into account a lag time between a precipitation event and groundwater tungsten level. These data also suggest that the concentration of tungsten in the soil pore-water declines with depth. We think this is due to dilution but it is also possible some of the tungsten is undergoing changes in speciation as it moves through the soil to a form that is less mobile and potentially adsorbing to soil. Our ongoing Phase II adsorption/desorption experiments should provide some insight on this question.

Figure 4. Tungsten results for deep lysimeters and MW-72S located at Bravo Range.



Drive-Points

As indicated in Table 5, eight temporary drive-points were installed as part of Phase II of the Tungsten Study with their locations determined through consultation with CENAE, IAGWSP, and the regulatory agencies. Figure 2 shows the locations of the three drive points installed on B Range. DP-1 is located on the B Range floor between the berm face and the firing point and approximately half way between MW-72S and the northern end of the range. DP-8 is located behind the firing line approximately half way between MW-72S and the southern end of the range. The drive-point at DP-7 is located downgradient of MW-72S (west), approximately half way between MW-72S and the BP-1 well. An insufficient quantity of water was recovered from DP-7 to analyze.

Figure 3 shows the locations of the five drive-points on the SW Ranges. Four of these (DP-2, 3, 4, and 5) were drilled along the down-gradient side (northwest) side of the range to determine if tungsten was present in the water and migrating away from the SE/SW Ranges (Table 7). An insufficient quantity of water was recovered to analyze samples from DP-3 and DP-4. One drive-point (DP-6) was installed on the SE Range down-gradient and 10 m (30 ft) from a pop up target.

Depth to water was approximately 30 m (100 ft). The drill crew marked the rod in one-foot increments as they approached the water depth. They were instructed not to exceed the rig or rod capacities (i.e. stop before rod failure) unless the bite was close to the water depth and the drive rod was still progressing downward (albeit slowly). Drilling was slowed down near 30 m to ensure we sampled at the water table. In some cases rods and screens were left in place overnight so as to collect sufficient water. The drive-point drill rods were steam-cleaned at Geoprobe and were cleaned again before drilling. An equipment blank was collected from the drill rods and indicated no detectable tungsten. The drill rods were cleaned between each drilling location.

Drive-point water samples were collected at 0-0.6, 0.76-2.29, and 2.29-3.81 m below the water table (bwt) (0-2, 2.5-7.5, and 7.5-12.5 ft bwt). Unfiltered and filtered water samples were sent to ERDC-EL for tungsten and metal analysis. Filtered water samples were sent to NAU for confirmation analysis. The IAGWSP did not collect a split sample for analysis by STL, although the Massachusetts Department of Environmental Protection did obtain a split sample. ERDC-CRREL has not been provided with this data so it is not included in this letter report.

All of the water samples from the drive-points, with the exception of DP-2, located on the SW Range, had no detectable tungsten (Table 7, Appendix C). The tungsten concentration as determined by ERDC-EL at DP-2 at the water table was 1.1 µg/L in the unfiltered water sample, although both NAU and ERDC-EL report no tungsten in the filtered sample (Table 7, Appendix C). ERDC-EL reanalyzed the unfiltered sample and obtained the same concentration of 1.1 µg/L tungsten. A split of this unfiltered sample was sent to NAU for analysis. NAU experienced interference issues with the unfiltered sample and initially reported an estimated value of 91 µg/L. Reanalysis of this sample yielded a reported value of <15 µg/L. Due to the interference issue, NAU was unable to report a lower reporting limit. NAU also filtered this sample and analyzed the filtrate and

did not detect any tungsten. In the second sampling interval at DP-2, NAU reported a filtered tungsten value of 4.3 µg/L, although ERDC-EL reported no tungsten in the filtered or unfiltered sample. NAU re-analyzed this sample and reported a tungsten value of <3.0 µg/L but indicated they could report no lower due to interferences. As will be discussed in the next section a monitoring well was installed at the DP-2 location with a screen placed at the same elevation as the drive-point detections of tungsten. No tungsten was detected in this monitoring well, suggesting the drive-point detections of tungsten (particularly the unfiltered samples) were likely false-positives due to interferences associated with the suspended solids.

Monitoring Wells

Before selecting the location of the permanent groundwater monitoring wells, researchers from USAEC, ERDC-CRREL, USACE-NAE, IAGWSP, USGS, EPA, and MADEP reviewed all of the drive-point data. Three groundwater wells were installed in B Range at the drive-point locations BP-1 and BP-2C. Two wells were installed at C Range with one at drive-point location CP-3. Three wells were installed at the SE/SW Ranges (Figures 2 and 3). One well each was installed at drive-point at the DP-2 and DP-5 locations with a third well placed downgradient of the firing point at T Range, which is also downgradient of the SE/SW Ranges.

An NAE contractor used a high torque auger rig to drill holes in which to install 5-cm (2-inch) diameter PVC pipe and 3-m (10-foot) long slotted screens. A single screened monitoring well was installed per location. Each well screen was 10-feet long. Wells were installed such that approximately 2 feet of the screen was above the water table with approximately 8 feet submerged in the groundwater. The monitoring wells have dedicated bladder pumps compatible with the controllers used by the IAGWSP contractors. An NAE contractor developed the wells and each was surveyed for elevation. All wells were installed and developed as per IAGWSP standard operating procedures (SOPs) specified in the IAGWSP Quality Assurance Project Plan (QAPP) (ECC 2003).

The MODFLOW 96 MMR-10NW Regional Groundwater Flow Model and MODPATH were used to simulate groundwater flow and predict the elevation of water at specific locations. The EPA's plume diving calculator, (http://www.epa.gov/athens/learn2model/part-two/onsite/diving.htm), was also used to determine if well screens were placed at the correct depth to intercept groundwater originating from the ranges most likely to have tungsten. All of the samples were colleted by CENAE's contractor and the samples sent to STL for analysis for the IAGWSP. Some sample splits were collected and analyzed by ERDC-EL for our study. The majority of sampling events involved collection of a filtered and unfiltered sample. The detection limit for tungsten was approximately 0.2 µg/L with a 1 µg/L reporting limit for all samples for both ERDC-EL and STL. Lower detection limits were achievable with the monitoring well samples due to less turbid water as compared to the drive-points and lysimeters.

Two monitoring wells (MW-455S and MW-490S) were installed at B Range for our study. Table 8 shows the tungsten results for these wells. In the two sample splits provided to ERDC-EL for our study no tungsten was detected in the filtered or unfiltered sample. However, STL consistently reported tungsten at an estimated level of 1.4 µg/L in the unfiltered sample for the first three sampling events. Although, in the later two sampling events STL reported no tungsten present in the filtered or unfiltered samples. It is our understanding that STL changed their sample preparation procedures prior to the two later sampling events to be consistent with ERDC-EL's methodology.

Monitoring well, MW-456S and MW-491S, were installed at the C Range. MW-456S was sampled three times by STL for the IAWSP. In the first sampling event STL reported a tungsten detection of 2.6 µg/L in the filtered sample with no tungsten in the unfiltered sample (Table 8). Unfortunately, split samples were not provided to our study for comparison analysis. The two subsequent sampling events and analysis by STL for the IAGWSP indicated no tungsten present. No tungsten was detected in MW-491S by STL or by ERDC-EL in the split sample provided for our study.

At the SE/SW Range split samples provided to ERDC-EL as part of our study from MW-465S and MW-466S had no detectable tungsten. In contrast, STL analysis for the IAGWSP show some low-level detections of tungsten in the early sampling events and no tungsten in later events. As reported in Clausen et al. (2007) the quality assurance/quality control data for ERDC-EL indicated no tungsten present in laboratory or field blanks.

Based on the seven water samples analyzed by ERDC-EL, there is no evidence of tungsten levels above the reporting limit in monitoring wells located immediately down-gradient of the berms at B and C Ranges and the down-gradient edge of the range floor of the SW Range.

In addition to sampling the monitoring wells installed as part of the Tungsten Phase II SAR Study the CENAE/IAGWSP contracted directly with NAU and ERDC-EL to provide analysis on split samples for several IAGWSP wells. These data are not reported in this letter report but are available from the CENAE/IAGWSP. Also, CENAE conducted an extensive blind round robin analysis between ERDC-EL, NAU, STL, and the MADEP laboratories. These data are not reported in this letter report but are available from the CENAE/IAGWSP.

Table 8. Monitoring well results for the Tungsten Study Phase II Wells.

CONCLUSIONS

Tungsten water concentrations are reported to be less than our 1 µg/L reporting limit in background wells; so tungsten concentrations above this level are likely due to training with bullets containing tungsten. Lysimeters continue to show detections of tungsten. However, the tungsten concentrations in the lysimeters decrease with increasing depth indicating possible sorption onto the soil and/or dilution. During phase II, through the sampling of additional wells and drive points, we were unable to identify any zones of elevated tungsten in the aquifer in the vicinity of B, C, or SE/SW Ranges.

Appendix A

Groundwater Monitoring Wells Sampled

Existing IAGWSP Analyzed by ERDC-EL
in Phase I Tungsten SAR Study

MW-72S (located on B Range)
MW-123M1 (located down-gradient of B and C Range)
MW-135M1 (background well)
MW-404S (background well)

The data for these wells has been previously provided in Clausen et al. 2007 with additional Phase II ERDC-EL data provided in this letter report in Table 1. These wells were sampled for the IAGWSP with sample splits provided to ERDC-EL and analyzed as part of the USAEC managed Tungsten SAR Study. STL generated data is not provided in this letter report but is available from CENAE/IAGWSP.

IAGWSP Installed SAR Wells

MW-174S (Former D Range)
MW-467S (Tango Range)
MW-489S (Tango Range)
MW-468S (Echo Range)
MW-470S (Gulf Range)
MW-471S (Juliet Range)
MW-472S (Juliet Range)
MM-473S (Kilo Range)
MW-474S (Kilo Range)
MW-475S (Former B Range
MW-476S (Former B Range)
MW-492S (Oscar Range)

These wells are not part of the USAEC managed Tungsten SAR study. However, the CENAE contracted with NAU and ERDC-EL (separately from USAEC) to perform analysis of split samples for some of the sampling events. The ERDC-EL laboratory generated data relating to ranges studied by in the USAEC in phase II of their Tungsten SAR study is provided in Appendix D for completeness. The STL generated data is not provided in this letter report but is available from the CENAE/IAGWSP.

Existing IAGWSP Wells Sampled to Measure Background

MW-05M2
MW-07M2
MW-62S
MW-67S
MW-71M1
MW-79M2
MW-151S
MW-254M2
MW-280M2
MW-357S
MW-404S

These wells were sampled by ECC for CENAE/IAGWSP and analyzed by STL with split samples provided to NAU. The NAU analysis was conducted as an activity under the Tungsten SAR Study. The NAU data is provided in this letter report in Table 3. The STL generated tungsten data is presented in Table 3. Additional analytical results are not provided in this letter report but are available from the CENAE/IAGWSP.

Tungsten SAR Study Phase II Wells

MW-455S (B Range)
MW-490S (B Range)
MW-491S (C Range)
MW-456S (C Range)
MW-465S (SE Range)
MW-466S (SE Range)
MW-467S (Tango Range)

These wells were installed for ERDC-EL by CENAE for the Tungsten SAR Study. The wells were sampled by ECC for CENAU with split samples provided to ERDC-EL. These ERDC-EL analysis were not part of the USAEC Tungsten SAR Study but are provided in Appendix D for the convenience of the reader.

Abstract: Tungsten was detected in soil and groundwater beneath the Bravo Small Arms Range (SAR) at Camp Edwards, Massachusetts. This discovery prompted additional studies to assess tungsten's fate-and-transport. Installation of drive points and groundwater monitoring wells at three SARs [Bravo (B), Charlie (C), and South East/South West] indicate that groundwater contamination is restricted to B Range. Although tungsten is still present in groundwater monitoring well MW-72S at Bravo Range, concentrations have dropped significantly since the removal of soil and have stabilized at a less than 2 µg/L concentration. Soil remediation consisted of removal of all berm soil that contained tungsten with a level greater than 150 mg/kg. Similarly, shallow lysimeters installed at B, C, and India Ranges also indicate a decline in tungsten levels post-soil removal. Deep lysimeters at B range, installed after soil removal activity, indicate that tungsten is present in pore water at least 7.6 meters below ground surface.

Batch and column laboratory studies performed as a part of this program demonstrated that tungsten metal in contact with water readily releases dissolved species, and soil partition coefficients (K_d) do not stabilize in batch studies for 30 to 60 days. The K_d values are highly variable, range from 18 to 477 L/kg, and are dependent upon the length of contact time. The rate of dissolution from a tungsten particle appears to range from 0.022 to 0.067 mg/day. These findings indicate that metallic tungsten and tungsten oxides are rapidly dissolved under high-intensity precipitation events and are transmitted through the vadose zone soils as tungstate and polytungstate species. In contrast, under low-precipitation intensity events, the rates of dissolution and infiltration are lower, resulting in a greater degree of tungstate and polytungstate sorption. Consequently, the release pattern of tungsten in the aquifer at Camp Edwards will be in a slug- or pulse-type fashion and dependent on infiltration rates. Thus, a contiguous area of groundwater contamination is not expected. Additionally, the capacity for Camp Edwards soils to adsorb tungstate is high. If tungstate reaches groundwater, it will continue to be adsorbed by the aquifer matrix, resulting in limited migration from the source area.

Preliminary water speciation studies indicate that the presence of tungsten to a depth of 4.6 m in the vadose zone is comprised of tungstate and polytungstate species, indicating the polymerization of tungstate. Tungstate, however, is the only species found in groundwater. Polytungstate migra-

tion is seemingly attenuated by adsorption processes that prevent it from reaching groundwater.

Conventional K_d modeling approaches seriously under predict tungsten migration at Camp Edwards SARs. Clearly, factors that control tungsten mobility are not included in these models. Importantly, soil geochemical conditions, such as redox potential and pH, affect tungsten speciation and its interaction with the subsurface. More research is required to determine the exact mechanisms responsible for tungsten migration at SARs, but data from this study suggest that implemented remedial actions at Camp Edwards have significantly limited the potential for widespread contamination from use of tungsten training rounds.

Preface

This report was prepared by Jay L. Clausen, Dennis Lambert, Ronald Bailey, Susan Taylor and Sue Bigl, Biogeochemical Sciences Branch (BSB), U.S. Army Engineer Research and Development Center (ERDC), Cold Regions Research and Engineering Laboratory (CRREL), Hanover, New Hampshire. Additional authors include Anthony Bednar, Environmental Chemistry Branch, Environmental Laboratory (EL), ERDC, Vicksburg, Mississippi, and Michael Kuhlbrush, U.S. Army Corps of Engineers, New England District, Concord, Massachusetts.

The U.S. Army Environmental Command provided funding for this work. Alan Hewitt and Dr. Terrance Sobecki, CRREL, provided technical reviews.

This report was prepared under the general supervision of Terrence Sobecki, Branch Chief, BSB, CRREL; Dr. Justin Berman, Chief, Research and Engineering Division, CRREL; and Dr. Robert E. Davis, Director, CRREL. The Commander and Director of the ERDC is Col. Gary E. Johnston. The Director is Dr. Jeff Holland.

1 Introduction

The U.S. Army Corps of Engineers, Environmental Research and Development Center (ERDC), Cold Regions Research Engineering Laboratory (CRREL), Hanover, NH, was tasked by the U.S. Army Environmental Command (USAEC) to assess fate-and-transport properties of tungsten that has leached from tungsten/nylon bullets. The tungsten/nylon bullet was developed by the U.S. Army as a more environmentally-friendly replacement for the lead bullet (SERDP 1997). Metallic tungsten was considered environmentally benign because researchers believed it was essentially insoluble, with little or no mobility in soil and water. However, previous studies at the Massachusetts Military Reservation (MMR) at Camp Edwards demonstrated that metallic tungsten used in these projectiles was mobile under some conditions (Clausen et al. 2007a, b).

Prior to 2000, the environmental fate of tungsten had not been examined in much detail because of a lack of suitable analytical techniques and a general belief that tungsten was relatively insoluble and inert. This belief persisted even though metallurgical literature had suggested tungsten might be relatively soluble under appropriate conditions of pH and redox potential (Osseo-Asare 1982).

We are now aware that intact (or partially intact) bullet fragments deposited in metallic form can be chemically oxidized into soluble ions, which are subject to leaching with percolating water. Under oxidizing conditions, the stable and soluble forms of tungsten are tungstate (WO_4^{2-}) or oxide complexes in the +6 oxidation state. The study of tungsten's environmental behavior is complicated by its propensity to polymerize; reactions favored at lower pH and higher tungsten concentrations. The oxidizing and relatively low pH soil environment at Camp Edwards is favorable for the formation of tungstate and polytungstates (Dermatas et al. 2004; Koutsospyros et al. 2006).

Several recent studies have discussed tungsten mobility in the environment. These include corrosion of tungsten and its alloys under environmental conditions (Ogundipe et al. 2004), bioaccumulation in plants (Wilson and Pyatt 2006), toxicity to bacteria and plant species (Strigul et al. 2005), and migration through the vadose zone of a sandy soil (Clausen and

Korte, in review). Because soluble forms are typically anionic, the environmental behavior of tungsten is distinctly different than most other metal contaminants (lead, copper, and zinc) associated with military small arms ranges (SARs). For example, phosphate has been added to training ranges to limit lead migration by formation of insoluble lead phosphates (Bricka et al. 2004) at Camp Edwards. In contrast, laboratory data (Xu et al. 2006) suggest phosphate and tungstate will compete for adsorption sites or react to form soluble complexes. Addition of phosphate, while it fixates lead, may enhance tungsten mobility. In addition, Bednar et al. (2008) found that tungstate polymerization occurs over time and apparently decreases mobility. However, these researchers noted a lack of precise definition of exact species and their stability.

Camp Edwards was chosen as a tungsten study site because tungsten/nylon projectiles have been fired there since October 1999, and detailed records are available regarding the number of bullets fired per range (Clausen et al. 2007a, b). The initial study reported levels of tungsten in soil and soil pore water at three evaluated ranges (Bravo (B), Charlie (C), and India (I) Ranges). Tungsten concentrations in surface soils ranged as high as 2,080 mg/kg. Samples from lysimeters installed into range berms showed tungsten levels in the soil pore water up to 400 mg/L. Samples from monitoring well MW-72S, located approximately 10 m downgradient of the berm on B Range, contained tungsten at levels between 0.005 and 0.560 mg/L. These findings raised concerns that tungsten was migrating away from the SAR and could affect downgradient water supplies.

This report describes supplemental laboratory experiments and fieldwork assessing the fate-and-transport of tungsten at Camp Edwards SARs. Information is provided to assist the following organizations in future decisions regarding tungsten's environmental behavior: the U.S. Army, U.S. Army Environmental Command (USAEC), Impact Area Groundwater Study Program (IAGWSP), and Massachusetts Army National Guard (MAARNG). The information should also be valuable to organizations providing oversight or regulation for sites where tungsten has been used; e.g. the U.S. Environmental Protection Agency (USEPA), Massachusetts Department of Environmental Protection (MADEP), and the Environmental Management Commission (EMC).

The project team included:

- Technical Representative and Program Manager - Kimberly Watts (USAEC)
- Technical Project Manager – Dr. Bonnie Packer (USAEC)
- Principal Investigator – Jay Clausen (ERDC-CRREL)
- Field Coordinator – John Ehret (U.S. Army Corps of Engineers (USACE) New England District (CENAE)

All field activities were coordinated through John Ehret at the USACE–CENAE. Mr. Ehret was responsible for communicating with the Camp Edwards IAGWSP, coordinating with Massachusetts Military Reservation (MMR) subcontractors and informing Jay Clausen of any changes in field activities. Jay Clausen was responsible for communication with Kimberly Watts and Bonnie Packer of USAEC.

2 Objectives

Based on Phase I study efforts (Clausen et al. 2007a, b), the primary objective of this project was to further describe and explain the fate-and-transport of tungsten in the environment. The secondary objective was to determine the extent of tungsten migration from surface soils to groundwater at Camp Edwards by installing and sampling drive points, groundwater wells, and lysimeters. Evidence from one well, MW-72S on B Range, already demonstrated that tungsten migrated to the aquifer in less than 6 years. Drive points and groundwater wells installed for this work have the ancillary purpose of aiding the IAGWSP to further understand flow paths for both pore water and ground water at the SAR.

A third objective was to determine how quickly tungsten metal in tungsten/nylon bullets dissolved and moved through the soil. The degree of dissolution, sorption, and desorption was measured in drip experiments, standard batch tests, and column studies. Speciation of tungsten in water was examined with high performance liquid chromatography/inductively coupled plasma/mass spectrometry (HPLC/ICP/MS). Because tungsten can exist in multiple oxidation states and its speciation is poorly known, laboratory x-ray absorption spectroscopy is being used to identify and quantify the physical and chemical forms of tungsten in Camp Edwards soil cores. The soil speciation work was completed in February 2009 and documented in a supplemental addendum to this document.

The Phase II Study was divided into a series of tasks:

- Task 1. Prepare Work Plan (Clausen 2006).

- Task 2. Collect groundwater drive-point samples from several locations downgradient of the SARs (B and SE/SW Ranges) and install monitoring wells (B, C, and SE/SW Ranges) to assess the nature and extent of tungsten contamination.

- Task 3. Install lysimeter clusters at depths of 1.5, 4.6, and 7.6 m (5, 15, and 25 ft) bgs at one location at the B Range to assess the unsaturated zone transport of tungsten.

- Task 4. Determine tungsten dissolution rates from tungsten/nylon material via drip tests and with batch and column studies.

- Task 5. Perform adsorption/desorption laboratory batch and column studies to quantify the interaction of tungsten and lead with Maectite-treated surface soils, untreated surface soils, and subsurface soils under a variety of conditions.

- Task 6. Perform unsaturated zone modeling using data from Tasks 2, 3, and 4 to predict the rate of tungsten transport across the entire unsaturated zone; i.e. approximately 36 m (120 ft).

- Task 7. Perform groundwater modeling using data from Tasks 2 through 6 to determine the tungsten transport rate and the predicted extent in the saturated zone for all 12 SARs at Camp Edwards.

- Task 8. Determine the species of tungsten present in the environment (to be provided in an addendum report).

- Task 9. Complete Interim and Final Reports (this document) and perform project management and routine reporting tasks as appropriate.

3 Water Sampling and Analysis Methods

Water samples from the monitoring wells were collected in 500-mL plastic bottles by the Environmental Chemical Corporation (ECC), a contractor working for the CENAE on behalf of the IAGWSP. Four samples were collected from each well: 1) unfiltered and unpreserved; 2) unfiltered and preserved; 3) filtered and unpreserved; and 4) filtered and preserved. Samples were filtered in the field using an inline 0.45-µm filter. Preserved samples were collected in pre-acidified sample bottles containing nitric acid. All samples were then chilled to 4°C and shipped to the respective laboratory. Sample splits were provided to ERDC-Environmental Laboratory (EL) and Dr. Ketterer at Northern Arizona University (NAU). Drive-point samples and lysimeter samples for this study were collected without acid preservation, according to procedures for tungsten as previously described by Clausen et al. (2007a, b).

Water samples were tested for tungsten at ERDC-EL and NAU using inductively-coupled plasma mass spectrometry (ICP-MS) according to U.S. Environmental Protection Laboratory (USEPA) Method 6020. Samples were prepared according to USEPA Method 3050 with some modifications (Clausen et al. 2007b). Method 3050 typically involves preserving the water sample by adding a small volume of acid. However, acidification can influence tungsten solubility and speciation. Using concentrated acid is especially problematic when determining tungsten concentrations, because acids can form insoluble tungstates and polytungstates. Therefore, ERDC's procedure for tungsten analysis does not include field preservation with acid. Samples are simply chilled to 4°C and analyzed as soon as possible. For those samples not preserved upon collection, both NAU and ERDC-EL acidify the sample aliquot with nitric acid immediately prior to injection into the ICP-MS. This acidification stabilizes the other metals present so they can be assessed along with tungsten. The brief period of acid contact with tungsten prior to analysis is insufficient to cause formation of any insoluble tungstates and polytungstates.

During Phase I of the Tungsten SAR Study, many of the samples from lysimeters and monitoring wells were split and sent to both ERDC-EL and NAU for analysis. Evaluation of the data reported by Clausen et al. (2007b; Appendix A) demonstrated good agreement between these two independ-

ent laboratories. Consequently, a high degree of confidence exists in reporting tungsten concentrations as low as 1 µg/L.

The reporting limit for tungsten ranged from 1 to 15 µg/L, with a detection limit of about.2 µg/L for the Severn Trent Laboratory (STL), and 0.3 to 0.8 µg/L for ERDC-EL and NAU. Detection and reporting limits vary between sample runs because of differences in calibration as well as matrix interferences. In addition to testing for tungsten, ERDC-EL analyzed samples for antimony, arsenic, chromium, copper, iron, lead, manganese, molybdenum, nickel, selenium, vanadium, and zinc. Details on analysis and preparations performed by NAU and ERDC-EL are found in Clausen et al. (2007b).

4.0 Results and Discussion

4.1 Task 2 – Groundwater evaluation

4.1.1 Historical perspective – summarized Phase I groundwater results

During Phase I, water samples were collected four times from four monitoring wells (Appendix A) and analyzed for tungsten by two independent laboratories – ERDC-EL and NAU. Both laboratories reported similar tungsten concentrations for all samples (Clausen et al. 2007b).

Two of the monitoring wells were located downgradient of SARs where tungsten rounds had been fired (MW-72S and MW-123S), and two wells (MW-135M2 and MW-404S) were selected to evaluate the background concentration. One down-gradient well, MW-123, had no tungsten above the reporting limit of 1 µg/L (Clausen et al. 2007b). Similarly, neither background well contained tungsten above 1 µg/L. In contrast, tungsten was detected in MW-72S, located on the B Range floor, approximately 10 m downgradient of the impact berm. The first two samples, which were collected on December 15, 2005 and February 8, 2006, had tungsten concentrations of 15 and 25 µg/L, respectively (Table 1).

Because of tungsten detections in December 2005 and February 2006, the Governor of Massachusetts ordered discontinuation of the firing of tungsten rounds in February of 2006. Removal of soil containing more than 150 mg/kg of tungsten took place between May 10, 2006 and June 21, 2006. A sample from MW-72S collected on May 10, 2006 showed an increase in tungsten concentration to 560 µg/L. At the time this water sample was collected, soil had not yet been removed from Bravo Range. The soil removal project spanned several weeks and consisted of removal of soil containing more than 150 mg/kg tungsten from the berms at B, C, and I Ranges (and other locations). A sample collected from MW-72S at the completion of the soil removal project (J2 documents open at same time June 21, 2006), showed tungsten had decreased to approximately 5 µg/L (Table 1). Ongoing sampling by the IAGWSP in 2007 and 2008 indicates concentrations have continued to decline and are presently less than 2 µg/L, suggesting surface soil removal activity was successful in mitigating tungsten release (Koenig 2008).

4.1.2 Phase II groundwater monitoring installations

Because results from Phase I showed tungsten had migrated to the aquifer in less than 6 years (based on data from well MW-72S on B Range; Clausen et al. 2007a, b), objectives for this Phase II investigation were to examine mechanisms by which tungsten migrated from surface soil to groundwater and to assess the extent of transport in the aquifer. To delineate the extent of tungsten migration at B, C, and SE/SW Ranges, eight drive points (temporary sampling points obtained with a Hydropunch-type sampler) and eight groundwater wells were installed in the fall of 2006.

Table 1. Summary of tungsten results for MW-72S (located on Bravo Range) and MW-123S (located downgradient between Bravo and Charlie Ranges). All determinations used (ICP/MS).

Well Identification	Sample Date	Tungsten Concentration (µg/L)

MW-123S	5/10/06	NS	< 1	< 1	NS

Dup – duplicate; NA – not analyzed; NS – not sampled.

The drive points, lysimeters, and monitoring wells were installed in accordance with the draft Work Plan (Clausen et al. 2006). Drive-point and well locations on B Range were based on results from MW-72S and input from CENAE, IAGWSP, and regulatory agencies. Three drive points were installed at B Range and five at SE/SW Ranges (Table 2; Figures 1 and 2). Of the six originally planned monitoring wells, two were installed at B Range, one at C Range, and three at SE/SW Ranges. Because tungsten was not detected in any new drive points or monitoring wells, and drilling costs were lower than anticipated, two additional monitoring wells (one each at B and C Ranges) were installed in the third quarter of fiscal year 2007.

Table 2. Location and number of lysimeters, drive points, and monitoring wells installed in the Phase II Tungsten SAR Study.

Range	Deep Lysimeters	Drive Points	Monitoring Wells
Bravo	3	3	3
Charlie	0	0	2
SE/SW	0	5	3
Total	3	8	8

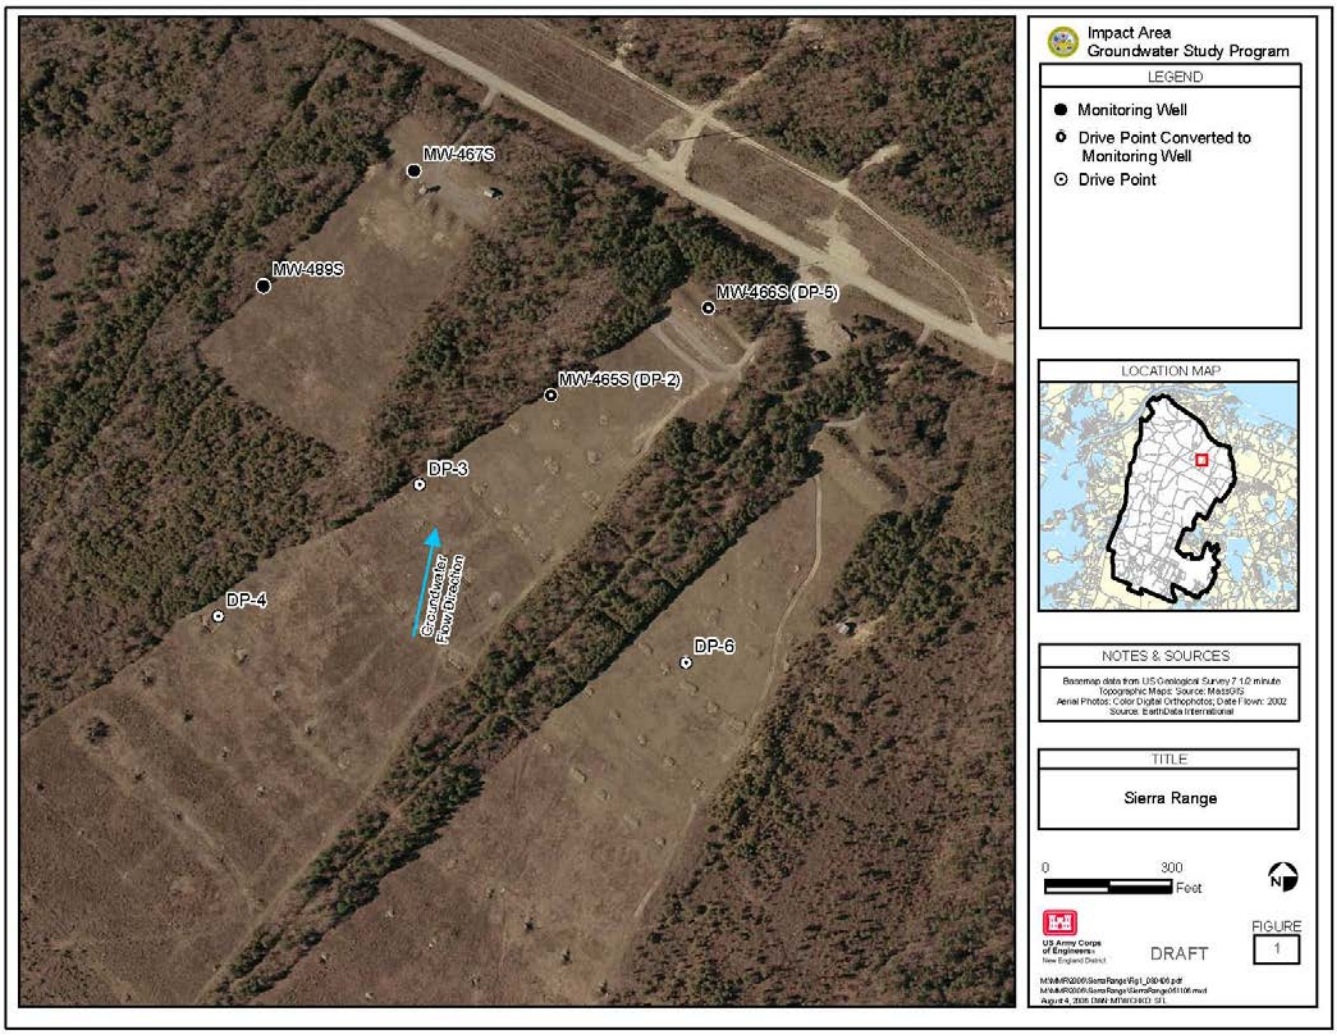

Figure 2. Location of drive points and monitoring wells at Southeast / Southwest Ranges.

4.1.3 Background well evaluation

Part of the Phase II study included an extensive evaluation of the tungsten concentration in 12 background wells. The wells evaluated were selected by ECC, a subcontractor to the CENAE. Figure 3 shows their locations, and Table 3 provides construction details. ECC collected samples between April 3 and April 26, 2007 and submitted them to NAU for analysis. The tungsten concentrations in each of the 12 monitoring wells shown in Figure 3 were below the NAU detection limit of 0.5 µg/L and below the reporting limit of 1 µg/L (Table 4).

4.1.4 Drive points

Eight temporary drive points (Table 2) were installed as part of Phase II of the tungsten study, with locations determined through consultation with CENAE, IAGWSP, and regulatory agencies. The drive-point drill rods were originally steam cleaned by the provider and also cleaned again just prior to drilling. An equipment blank sample collected from the drill rods showed no detectable tungsten. Drill rods were also cleaned between each drilling location.

Figure 1 shows locations of the three drive points installed on B Range. Drive-points DP-1 and DP-8, located on the northern and southern portion of the range, were placed in positions to assess whether tungsten was migrating into groundwater along the length of the berm face. DP-1 was located on the B Range floor between the berm face and the firing point, approximately half way between MW-72S and the northern end of the range. DP-8 was located behind the firing line approximately half way between MW-72S and the southern end of the range. DP-7 was located downgradient of MW-72S (west), approximately half way between MW-72S and well BP-1. The intent of DP-7 was to determine whether tungsten had migrated downgradient of MW-72S. Unfortunately, DP-7 yielded an insufficient quantity of water for performance of chemical analyses. This drive point may have become clogged with sediment or did not penetrate the water table sufficiently because of refusal.

Figure 2 shows five drive-point locations at the SE/SW Ranges. Four of these (DP-2, 3, 4, and 5) were drilled along the down-gradient (northwest) side of the range to determine whether tungsten was present in water and migrating away from the Ranges (Table 5). The water yield from both DP-3 and DP-4 was insufficient to analyze. DP-6 was installed on the SE Range down-gradient and 10 m (30 ft) from a pop-up target.

Depth-to-water was approximately 30 m (100 ft) for each drive point. The drill crew marked the rod in 1-ft increments as the drill approached the saturated zone. The crew were instructed not to exceed rig or rod capacities (i.e., stop before rod failure) unless they were very close to the saturated zone and the drive rod was still progressing downward (albeit slowly). Drilling was slowed near a depth of 30 m to ensure samples were collected at the water table. In some instances, rods and screens were left in place overnight in order to collect sufficient water. The drill rig apparently was unable to advance the drive point to a sufficient depth at several locations, and therefore no water could be collected.

Drive-point water samples were collected at 0-0.6, 0.76-2.29, and 2.29-3.81 m below the water table (bwt) (0-2, 2.5-7.5, and 7.5-12.5 ft bwt) using a Waterra sampler. Unfiltered and filtered water samples were sent to ERDC-EL for analysis of tungsten and other metals. Filtered water samples were sent to NAU for confirmation analyses. A split sample was provided to MADEP for analysis. Field parameters (temperature, pH, dissolved oxygen, specific conductance, turbidity, and Eh or redox potential) were measured and water samples were collected in 500-ml plastic bottles at each location.

Samples designated for filtering were filtered at ERDC-CRREL and sent to ERDC-EL for analysis. ERDC-EL analyzed the water for tungsten and metals using ICP-MS, following the USEPA Method 6020 for sample preparation by EPA Method 3005. Metals analysis included antimony, arsenic, chromium, copper, iron, lead, manganese, molybdenum, nickel, selenium, vanadium, and zinc (Appendix B).

Additionally, a sample was collected at the water table (0-0.6 m bwt [0-2.5 ft bwt]) from DP-5 for the IAGWSP for STL analysis of semi-volatile organic compounds (SVOCs) and explosives. All other water samples from the drive points were shipped to ERDC-CRREL.

All water samples from the drive points, with the possible exception of DP-2 located on the SW Range had no detectable tungsten (Table 5). Appendix B details the metal concentrations in the drive-point samples. ERDC-EL reported that tungsten concentration in the unfiltered water sample from DP-2 at the water table was 1.1 µg/L. Neither NAU nor ERDC-EL reported tungsten in the filtered sample (Table 5; Appendix B). ERDC-EL re-analyzed the unfiltered sample and once again measured 1.1 µg/L of tungsten. A split of this unfiltered sample was sent to NAU for analysis. NAU experienced interference issues and initially reported an estimated value of 91 µg/L. Upon reanalysis, NAU reported the value as <15 µg/L, because they were unable to achieve their expected reporting limit because of interference from suspended solids. NAU also filtered this sample, analyzed the filtrate, and did not detect tungsten.

In the second sampling interval at DP-2, NAU reported 4.3 µg/L of tungsten in the filtered sample. In contrast, ERDC-EL reported no tungsten in either the filtered or unfiltered sample. NAU re-analyzed this sample, reported the amount of tungsten as < 3.0 µg/L, and stated they could not

achieve a lower reporting limit because of sample matrix interferences. As discussed in the next section, a monitoring well was installed at this location. The well screen was located at the same depth as these possible drive-point detections. Tungsten was not detected in this monitoring well, suggesting drive-point detections (particularly the unfiltered samples) were false-positives caused by interference associated with suspended solids.

Table 5. Summary of tungsten results from drive points.

Range	Drive Point ID	Depth (ft bgs)	Tungsten Concentration (µg/L)

4.1.5. Monitoring wells

Locations of permanent groundwater monitoring wells were selected after researchers from USAEC, ERDC-CRREL, CENAE, IAGWSP, U.S. Geological Survey (USGS), USEPA, and MADEP reviewed all drive-point data. Three wells were then installed in B Range at drive-point locations BP-1 and BP-2C; two wells installed at C Range were at drive-point locations CP-3 and CP-2 (Fig. 1). Three wells were installed at the SE/SW Ranges (Figure 2). One well each was installed at drive-point locations DP-2 and DP-5; a third well was placed downgradient of the firing point at T Range, which is also downgradient of the SE/SW Ranges.

All wells were installed by a CENAE contractor who used a high-torque auger rig. The contractor (ECC) installed and developed the wells following the Impact Area Groundwater Study Program (IAGWSP) standard operating procedures specified in the Quality Assurance Project Plan. Drill holes were sufficient to allow installation of 5-cm (2-in.) diameter PVC pipe and 3-m (10-ft) long slotted screens. A single monitoring well was installed at each location. For each well installation, approximately 2 ft of the 10-ft screen were above the water table; the remaining 8 ft were submerged in the groundwater. Monitoring wells were equipped with dedicated bladder pumps compatible with controllers used by the IAGWSP contractors. A CENAE contractor developed the wells, and each was surveyed for elevation.

A MODFLOW 96 MMR-10NW Regional Groundwater Flow Model and MODPATH were used to simulate groundwater flow and predict the elevation of water at specific locations. The USEPA plume-diving calculator, available at web site: (http://www.epa.gov/athens/learn2model/part-two/onsite/diving.htm), was also used to determine whether well screens were placed at the correct depth to intercept groundwater originating from the ranges most likely to have tungsten. All samples were collected by the CENAE contractor and were sent to STL for analysis for IAGWSP. Some sample splits were collected and analyzed by ERDC-EL as part of this study. The majority of sampling events included collection of a filtered and unfiltered sample. Water samples from monitoring wells were less turbid than drive-point and lysimeter samples and allowed for lower detection limits. The tungsten detection limit for ERDC-EL was nominally 0.2 µg/L, with a 1 µg/L reporting limit.

Table 6 lists tungsten results for wells MW-455S and MW-490S installed at B Range for this Phase II study. Tungsten was not detected in either the filtered or unfiltered samples in the two sample splits provided to ERDC-EL. At C range, the Phase II-installed monitoring well MW-456S was sampled three times by STL for the IGAWSP. In the first sampling event, STL reported a tungsten detection of 2.6 µg/L in the filtered sample and no tungsten in the unfiltered sample (Table 6). Unfortunately, split samples were not provided to ERDC for analysis. The two subsequent sampling events and analyses by STL for the IAGWSP indicated no tungsten was present. No tungsten was detected in the C Range Phase II well, MW-491S, by ERDC-EL in the split sample provided for this study.

At the SE/SW Range, split samples were provided to ERDC-EL from Phase II monitoring wells MW-465S and MW-466S. Neither well had detectable tungsten.

As reported by Clausen et al. (2007b), quality assurance/quality control data for ERDC-EL indicated no tungsten present in laboratory or field blanks. Thus, based on the seven water samples analyzed by ERDC-EL, no evidence of tungsten presence above the reporting limit was found in monitoring wells located immediately downgradient of the berms at B and C Ranges and the down-gradient edge of the range floor of the SW Range.

Detections of tungsten in MW-72S at B range were confirmed in filtered, unfiltered, acidified, and un-acidified samples by two independent laboratories using three different instruments/methodologies (Clausen et al. 2007b). Leaching of tungsten to groundwater from the B Range SAR was thus confirmed. However, samples collected prior to and after the highest reported value (560 µg/L in May 2006) suggest that tungsten elevation occurred during a limited time period. Oscillating concentrations of hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX) and perchlorate have been observed in monitoring wells downgradient of Demolition Area 1 at MMR and appear related to overall precipitation trends. The MW-72S anomalous value was possibly related to similar phenomena. Unfortunately, data are insufficient to determine whether the period of elevated tungsten lasted hours, days, weeks, or months. However, the zone of elevated tungsten is apparently limited and will migrate to the northwest away from the B Range. Although dispersion within the aquifer is low, the zone of contamination will disperse, and the foot print of elevated tungsten will grow with time. Concomitant with an increase in the area of elevated contamination, tungsten concentration will decline with time because of dispersion and subsequent dilution.

Table 6. Monitoring well results for Tungsten Study Phase II wells.

Well ID	Drive Point ID	Range	Sample Date	Filtered/ Unfiltered	Tungsten Concentration (µg/L)

NA = not applicable, NS = no sample, J = estimated value, F or U = filtered/unfiltered.

FD = field duplicate, LD = laboratory duplicate.

[1]STL results with multiple values indicate acidified and un-acidified samples.

Because tungsten projectiles were used for a short period of time (< 6 years), the maximum extent of contamination in groundwater downgradient of MW-72S can be estimated. Groundwater flow velocity is approximately 0.3m/day (1 ft/day) (AMEC 2001a), yielding a maximum horizontal distance of 2,190 ft [for the 6 years of tungsten presence], which conservatively assumes very rapid transport through the vadose zone. The flow rate through the unsaturated zone has not been measured, but model-

ing activities and discussions with USGS personal suggest that a conservative tracer would take several weeks to several months to move from the ground surface to the top of the water table. The lack of tungsten detections in the drive points and down-gradient wells at B Range confirm that any zone of elevated tungsten contamination is limited in size.

In addition to sampling monitoring wells installed as part of the Tungsten Phase II SAR Study, the CENAE/IAGWSP contracted directly with NAU and ERDC-EL to provide analysis on split samples for several IAGWSP wells. CENAE also conducted an extensive, blind, round-robin test between ERDC-EL, NAU, STL, and MADEP laboratories. These data (not reported here but available from the CENAE/IAGWSP) showed sufficient agreement among laboratories. Thus, analytical problems may be discounted when reviewing tungsten data.

4.2 Task 3 – Unsaturated zone evaluation

4.2.1 Historical perspective – summarized Phase I lysimeter results

Table 7 summarizes the lysimeter results for Phase 1 of the Tungsten SAR study (Clausen et al. 2007b). Concentrations as high as 400 mg/L were observed in lysimeters installed beneath the berm face. As reported previously, data from these shallow lysimeters were not consistent with respect to concentrations trends; some increased, others decreased, and still others showed no trend. Background concentrations of tungsten were generally reported as less than 0.2 mg/L.

4.2.2 Phase II shallow lysimeters

The Phase II shallow lysimeter task involved sampling the lysimeters remaining from Phase I. Several lysimeters were no longer available for Phase II sampling. When berm soils containing > 150 mg/kg tungsten were removed by the MAARNG, several of the lysimeters, including all of those at B Range, were damaged during soil removal. In addition, several lysimeters, including those at background locations, were damaged by winter freezing. Three undamaged lysimeters (MMR-18, 19, 20, and 21) were available for sampling at C Range, and two (MMR-9 and 12) were available at I Range.

B-range Phase 1 data are presented in Figure 4. The data indicate a decline in tungsten concentration with time.

Table 7. Shallow lysimeter Phase I tungsten results (mg/L).

At C Range, shallow lysimeters showed a weak tungsten-concentration decreasing trend prior to the cessation of training with tungsten projectiles (Figure 5). Tungsten concentrations remained low after the cessation of training and the soil removal project (April and June 2006). The lysimeters remaining after soil removal continued the declining tungsten-concentration trend.

Initial tungsten concentrations measured at I Range lysimeters were much lower than those for B or C Range because I Range had an order of magnitude fewer tungsten projectiles fired than the other two ranges (Figure 6).

The lowest tungsten level for lysimeter 9 occurred after the cessation of tungsten firing and soil removal, but the decrease was modest. Lysimeter MMR-12 was at a low level prior to and after cessation of training with tungsten projectiles.

Overall, shallow lysimeter results indicate that tungsten concentrations in the pore water decline after cessation of training and after the removal of soil. However, some tungsten remains in the pore water because of previous or continuing dissolution and transport through the shallow soil profile.

All shallow lysimeters sampled during Phase II remain in place and are presumably available for additional sampling. Although Figures 4 through 6 show precipitation amounts, there is no evidence of a trend for tungsten concentration that is attributable to precipitation. Whether this is a consequence of inadequate sampling frequency or lack of a relationship with precipitation is unknown. However, later laboratory experiments suggest a probable relationship between intensity and duration of rainfall and tungsten concentrations.

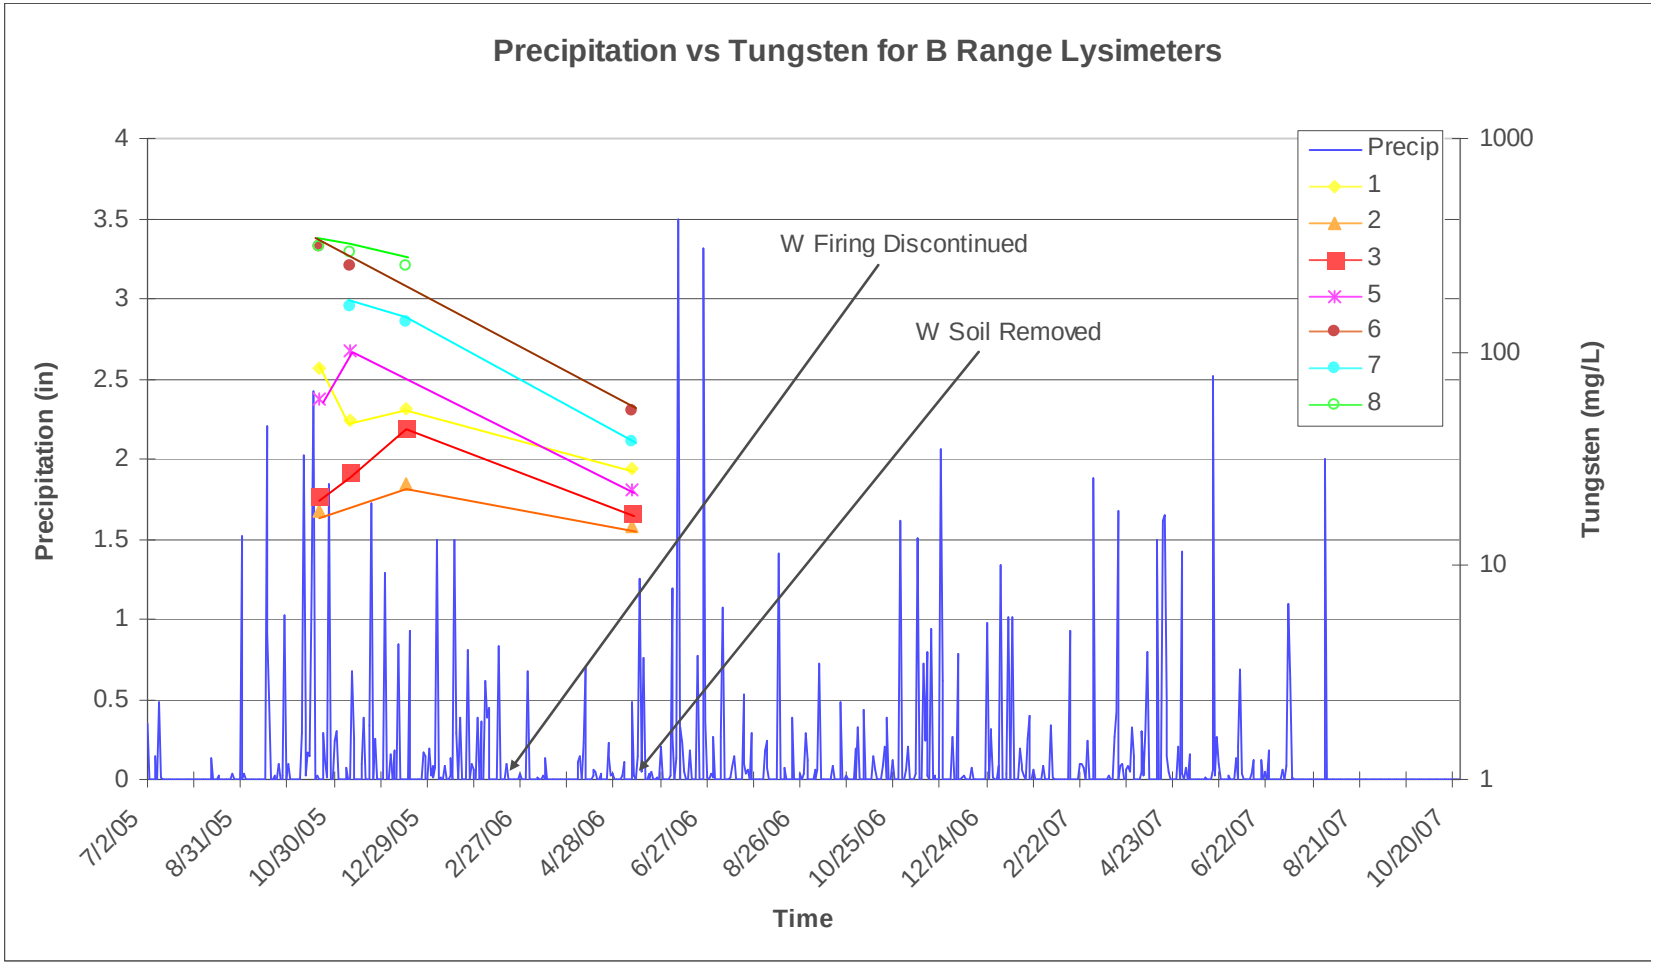

Figure 4. Tungsten concentrations at Bravo Range shallow lysimeters compared with precipitation events. Also noted are times when the use of tungsten (W) bullets ceased, and soil removal occurred.

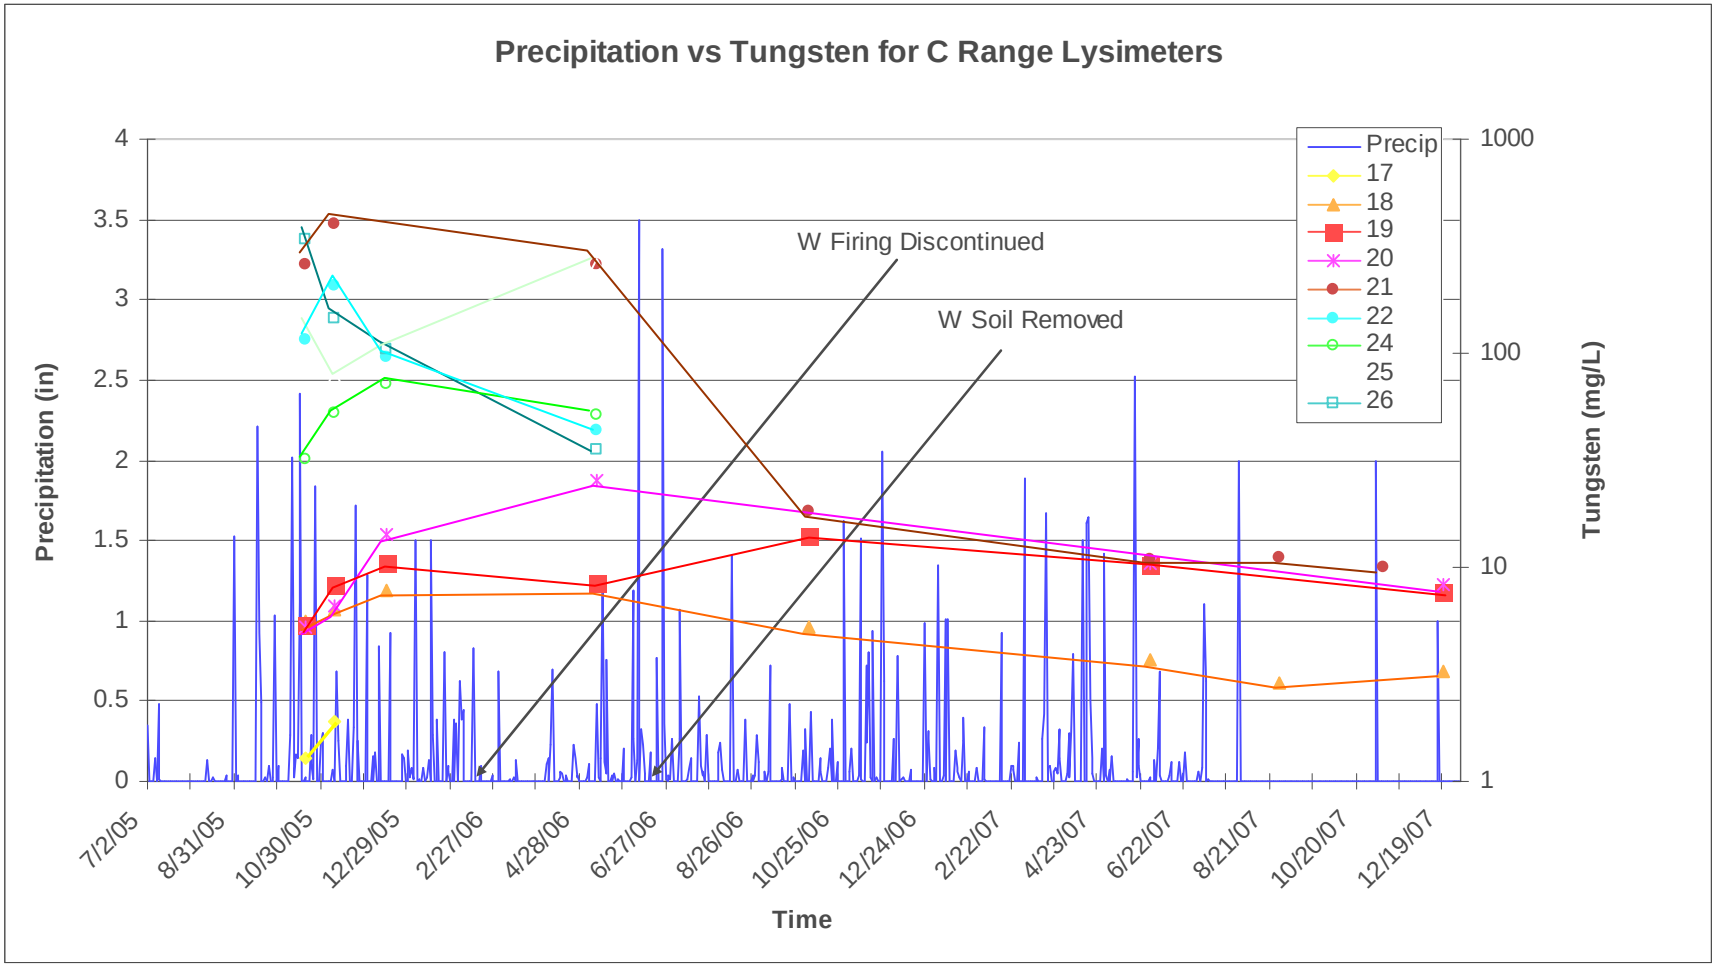

Figure 5. Tungsten concentrations at Charlie Range shallow lysimeters compared with precipitation events. Also noted are times when the use of tungsten (W) bullets ceased and soil removal occurred.

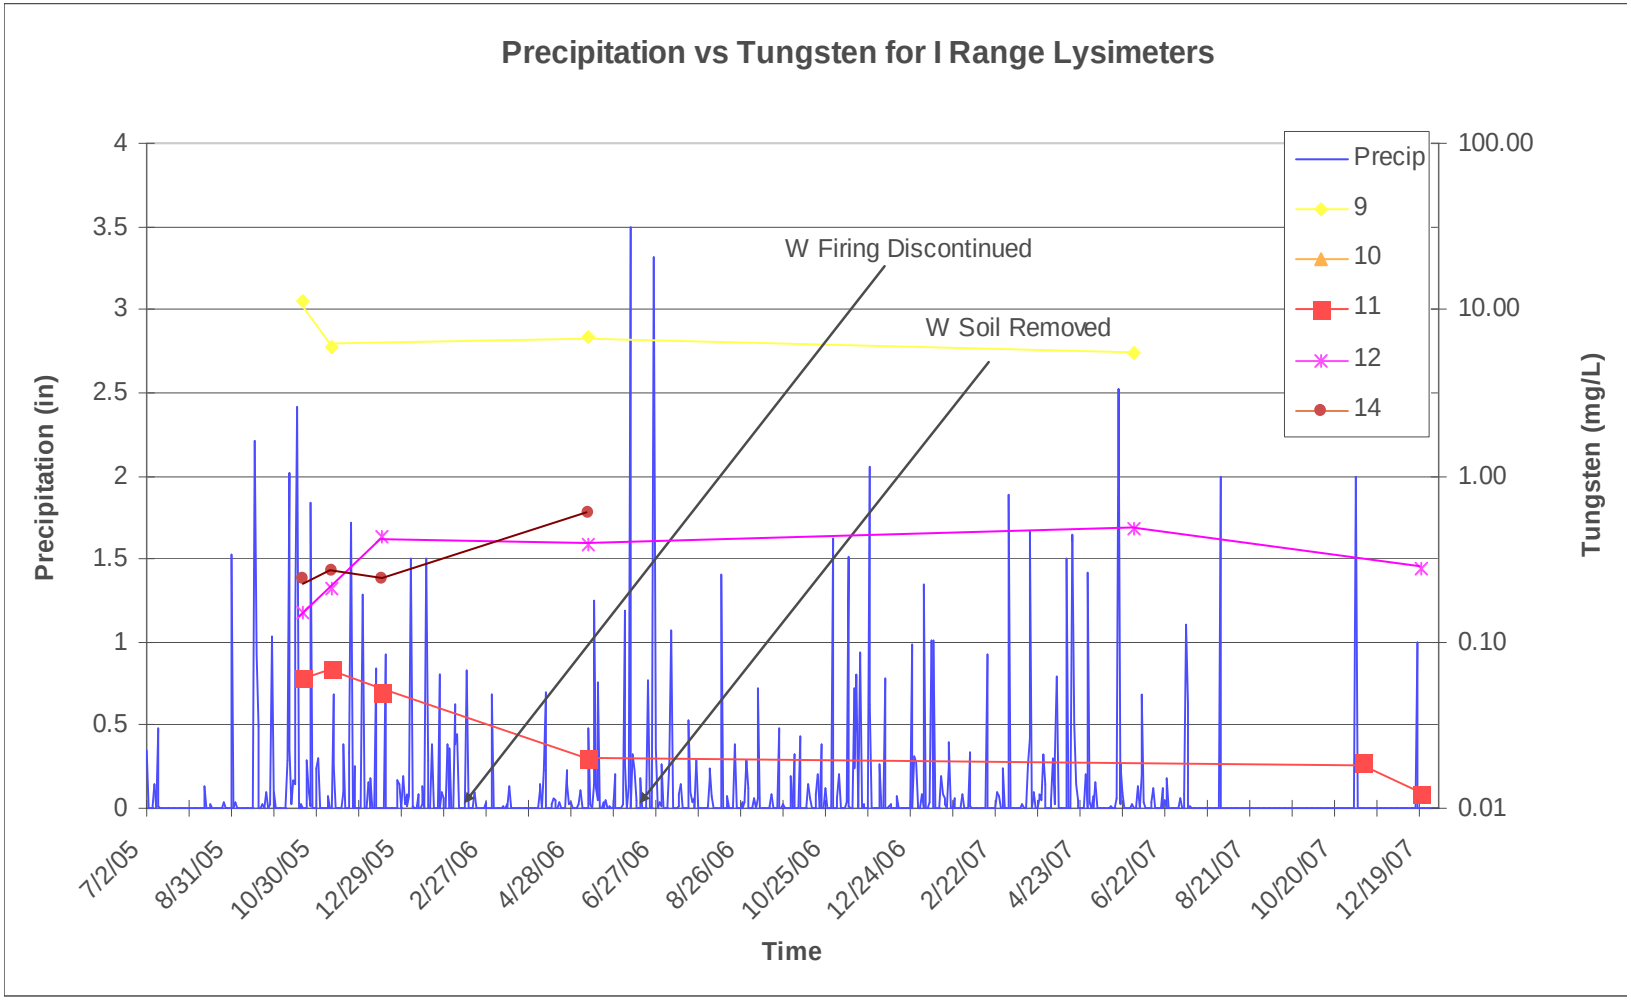

Figure 6. Tungsten concentrations at India Range shallow lysimeters compared with precipitation events. Also noted are times when the use of tungsten (W) bullets ceased and soil removal occurred.

4.2.3 Phase II deep lysimeters

Three deep lysimeters were installed beneath the former lower berm at B Range for the Phase II study. The purpose of these lysimeters was to assess unsaturated zone transport deeper in the soil profile than that observed with shallow lysimeters. This location had the highest tungsten concentration in surface soil prior to the removal project and was near MW-72S, which was the groundwater well with tungsten contamination. Depths for lysimeters were arbitrarily selected but were kept shallower than 10 m to allow sampling with a peristaltic pump. Lysimeter installation by the CENAE contractor was conducted with the same high-torque auger drilling rig used for installation of the monitoring wells. Holes were drilled to depths of 1.5, 4.6, and 7.2 m [5 ft (Lysimeter #30), 15 ft (Lysimeter #31), and 25 ft (Lysimeter #32)]. Lysimeters were sampled by ERDC-CRREL personnel using methods described in Clausen et al. (2007b). Analyses were performed by ERDC-EL.

These lysimeters have been sampled on six occasions (Table 8). Tungsten concentrations are highest in the shallowest (5 ft) lysimeter (#30). Tungsten was detected in the middle (#31, 15 ft) lysimeter, but concentrations were consistently less than 5 µg/L. Results for the deepest lysimeter, (#32, 25 ft), show a declining trend for the three samples recovered. Complete metal and field parameter results for these samples are provided in Appendix C.

Figure 7 shows the Camp Edwards precipitation record with superimposed tungsten concentrations from deep lysimeters and MW-72S at B Range. No cause-and-effect relationship is evident between precipitation and groundwater tungsten concentrations even when accounting for lag time between a precipitation event and a measured tungsten concentration. These data demonstrate that the concentration of tungsten in the soil pore-water declines with depth. The decline is a probable consequence of dilution, but some tungsten may be changing to a less-mobile form due to speciation and is adsorbing to soil (Bednar et al. 2008).

Table 8. Tungsten Phase II Study tungsten results (µg/L) for deep lysimeters at Bravo Range.

Lysimeter ID	Depth (ft)	Tungsten Concentration (µg/L)					
		11/3/06	2/28/07	5/3/07	8/27/07	11/08/07	12/19/07
30	5	660	NW	1,436	NW	NW	1,432
31	15	NW	< 2	4.1	NW	< 5	< 5
32	25	108	37	13	NW	NW	NW

NW – no water.

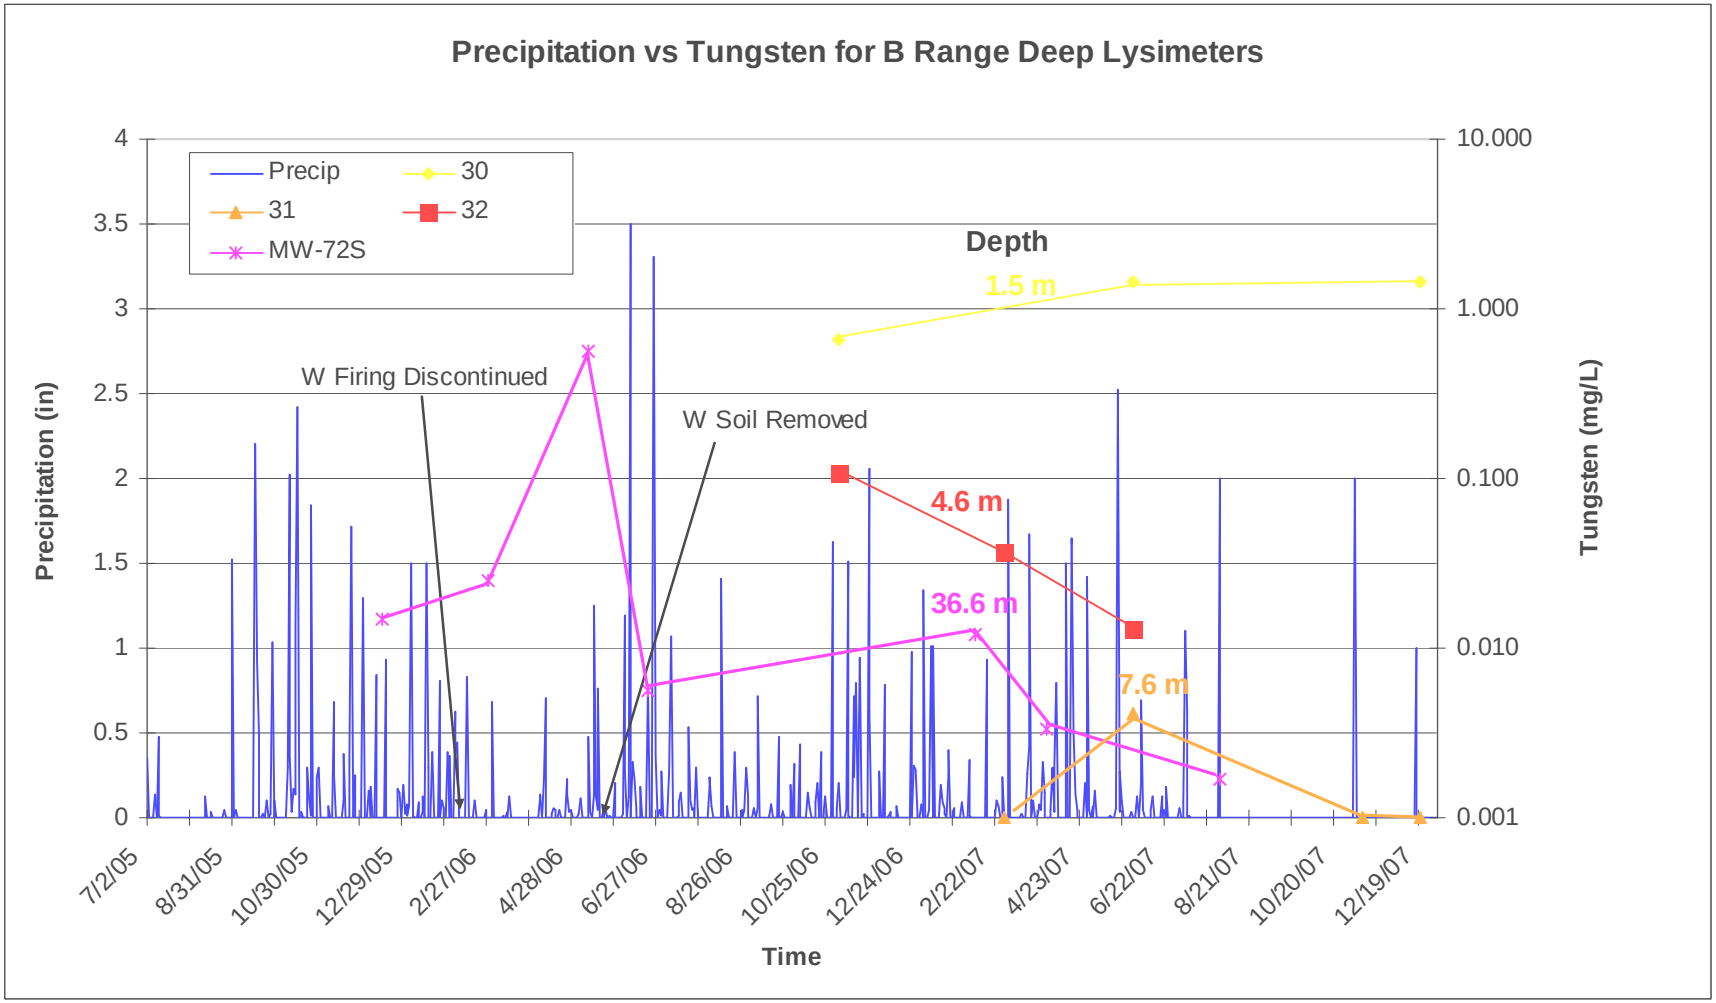

Figure 7. Tungsten concentrations from deep lysimeters and MW-72S at B Range compared with precipitation events at Camp Edwards. (Note the "X" m value represents the depth of the associated sampling device).

4.3 Task 4 – Dissolution studies

A month-long laboratory drip test and a year-long outdoor test with two bullet fragments were conducted to examine the rate at which tungsten dissolved from bullet fragments. A third batch test that involved both dissolution and desorption was conducted and is included in this section because the dissolution mechanism was likely predominant.

4.3.1 Laboratory drip test

In the 30-day laboratory drip test, DI was dripped onto a 102.98-mg tungsten nylon bullet fragment (Figure 8a), using a syringe pump (Fig. 8b). The drip rate, 0.51 mL/hr (~ 30-µL drops at a rate of 20 drops/hr), was equivalent to rain falling at 5.5 mm/hr (~0.2 in. /hr), resulting in an accumulation of approximately12 mL of water each day. Water flowed across the fragment and through a supporting glass frit into a clean scintillation vial. Analyses of the daily samples showed tungsten from the fragment was readily soluble (Figure 9). Concentrations of the daily dissolution varied between 4 and 13 mg/L, with an average of 7.2 ± 2.3 mg/L. An adequate mass balance for the experiment was demonstrated by weighing the bullet fragment at the end of the test. The fragment lost approximately 2 mg (102.98- 101.1 mg) of weight. Using the average volume of water, 11.2 mL, and assuming no error in the ICP-MS measurements, ~ 2.4 mg of tungsten was recovered in the water samples.

4.3.2 Outdoor exposure test

Two tungsten/nylon cores (Figure 10a) were set up outdoors in 4-cm diameter Buchner funnels on top of liter bottles (Figure 10b). The two tungsten/nylon cores, labeled W1 (dark in color) and W2 (silver in color), weighed 2.06 and 2.07 g, respectively. Rainwater or snowmelt that fell naturally onto the tungsten cores was collected in the bottles. Approximately every 2 weeks, the bottles were changed and the accumulated water volume was measured. Aliquots of the samples were then submitted for analysis. The results are shown in Figure 11. The W1 test was stopped in November 2007, and the W2 test is still ongoing. No water samples were collected over the winter (December 2007 through April 2008) when the experiment was covered with snow. The dark W1 core released tungsten immediately, and several months passed before leaching was observed from the silver W2. An assumption was made that darker W1 material was already oxidized to some extent and, therefore, was more readily dissolved. The silver color of the longer-reacting W2 fragment indicates pure tungsten metal. Thus, there was a time lag until sufficient surface oxida-

tion occurred for the fragment to begin to dissolve. In both cases, loss of tungsten from both the W1 and W2 cores approached 2 to 2.5 mg over a 3-month period, which was equivalent to a loss of approximately 0.022 to 0.028 mg tungsten per day. In the indoor test, the tungsten loss after 30 days was approximately 2 mg or 0.067 mg/day. The higher rate of tungsten loss from the indoor experiment is a function of a more constant and greater rate of water contact with the tungsten particulate and related surface area. Intact tungsten cores were used in the outdoor experiment, whereas in the indoor experiment a tungsten fragment from a core was utilized. Additionally, in the outdoor experiment, the precipitation contact was more irregular, which may have resulted in formation of tungsten oxides that dissolved more slowly.

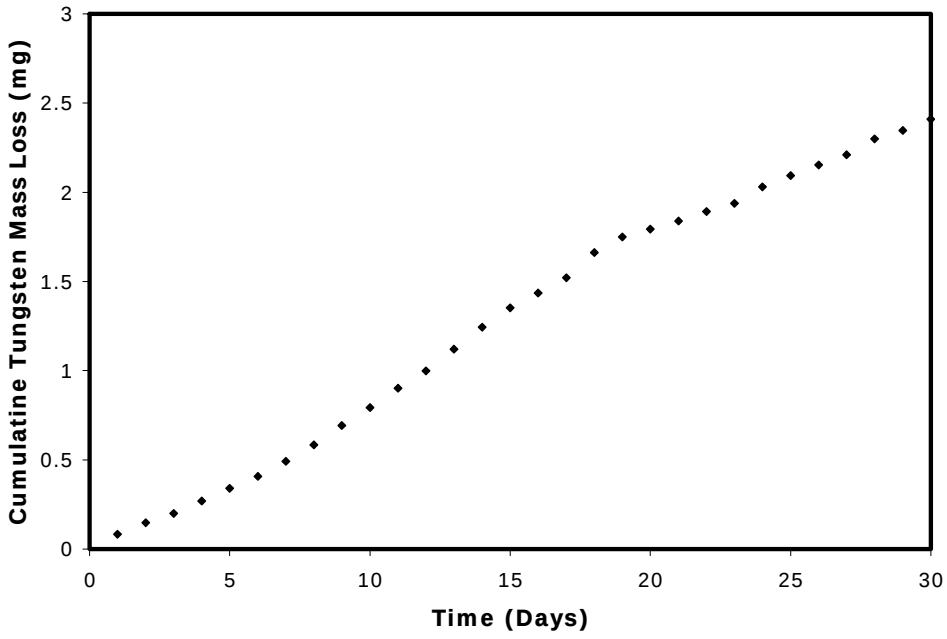

Figure 9. Tungsten mass dissolved (mg) in water samples taken over 30 days.

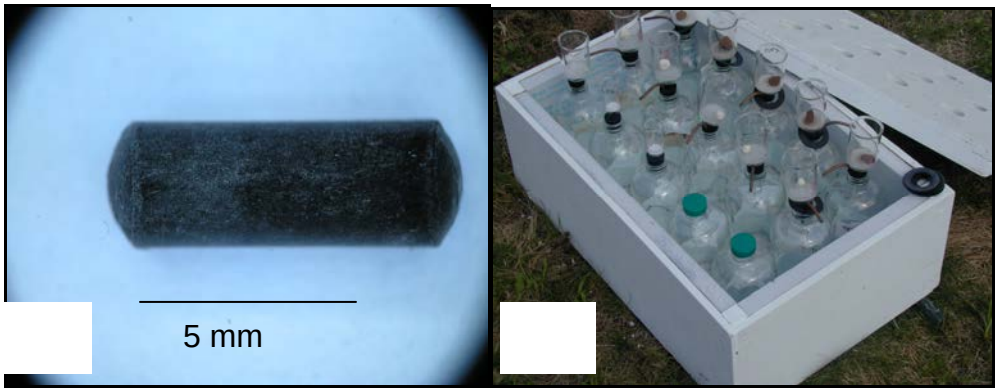

Figure 10. Photograph of a tungsten-nylon core (a) and outdoor experimental apparatus (b).

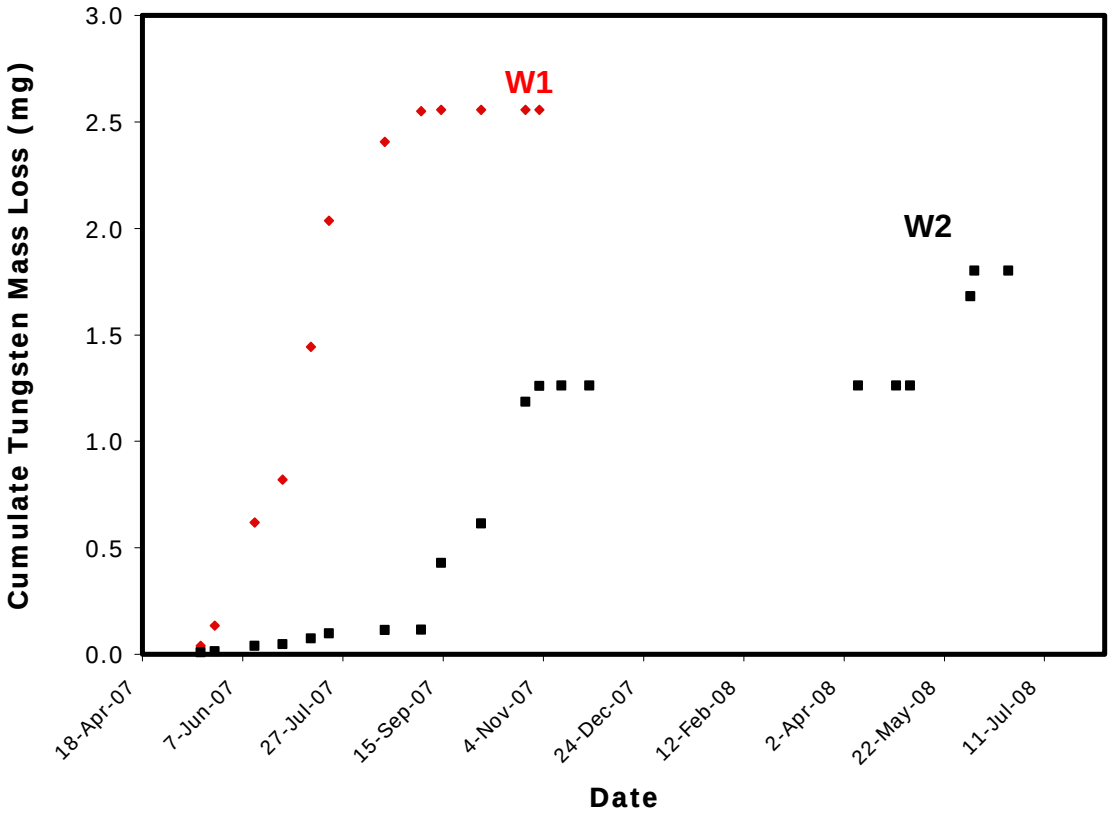

Figure 11. Cumulative mass loss of tungsten (W) in water samples collected from the bullet cores placed outdoors.

If one assumes that the outdoor loss rate of 2 mg every 30 days is representative, knows an intact tungsten/nylon core contains 2,010 mg tungsten, and is aware of soil concentration, a rough estimate of the persistence of tungsten as a particulate in soil can be determined. If a tungsten soil concentration of 2,000 mg/kg is assumed, this would be equivalent to

a single tungsten/nylon core. The persistence of the tungsten core is then approximately 83 years. However, we suspect that the rate of tungsten dissolution is dependent on surface area. An intact tungsten core has a much lower surface area than individual particles. The predominant form of tungsten present in the soil is believed to be comprised of tungsten particles ranging from 5 to 20 microns in size. However, the tungsten rate loss for varying size particles is unknown, suggesting that an 83-year value of tungsten persistence is conservative.

4.3.3 Batch test of contaminated soil

Seventeen soil samples contaminated with tungsten were collected from the SAR and tested. These soils might contain both metallic tungsten and tungsten sorbed to the soil surface, with the proportional distribution of each unknown. Consequently, this experiment is not strictly a dissolution or desorption test but rather a combination of the two processes. One assumed is that the mechanism for tungsten deposition and the rate of weathering in the field is the same for all samples. Therefore, a second assumption is that distribution of tungsten metal and tungsten sorbed onto the soil is essentially the same for each sample.

To begin the test, 4.5 g of soil that was previously sieved to remove the > 2 mm fraction was added to a 4-oz amber glass container. Seventy ml of deionized water (DI) was added to the 4.5 g soil. The samples were allowed to equilibrate for 24 hr on an orbital shaker table mixing at 100 revolutions per minute (rpm). After 24 hr the test samples were allowed to settle for 2 hr, and the aqueous solution was pipetted off and placed into a 100-ml plastic container and chilled prior to analysis.

Results from this test show that the amount of tungsten in solution is a function of soil concentration, and tungsten loss occurs in a typical concentration gradient pattern. A greater percentage of loss is observed in soil samples with higher tungsten soil concentrations, and a lower rate of loss (91 to 15%) occurs in soil with lower tungsten soil concentrations (Table 9). These results suggest initially that the rate of tungsten loss via either dissolution or desorption is high, but as concentration in the soil declines, the rate of loss also declines. Previous calculations of tungsten loss from a hypothetical, initial 2,000 mg/kg tungsten-contaminated soil in Section 4.3.2 may be an underestimation. Additionally, results from this experiment indicate that tungsten is rapidly dissolved or desorbed from soil.

Table 9. Dissolution/desorption batch test results.

Sample ID	Soil Concentration (mg/kg)	Measured Leachate Concentration (mg/L)	Mass Loss of Tungsten in 24 hr (mg)	Mass Loss of Tungsten in 24 hr (%)

4.3.4 Dissolution experiment summary

The amount of tungsten dissolving in each water droplet likely depends on the contact time between tungsten, water, and the amount of water passing by the tungsten particle. For the laboratory test, the tungsten fragment represented a large reservoir. Consequently, the water dripped on it depleted a small consistent portion of the available tungsten resulting in a constant loss rate. Tests conducted outdoors are more difficult to interpret because periods of tungsten dissolution are followed by periods of no apparent tungsten release. The latter observations are probably a consequence of varying temperature, humidity, air contact, and development of oxide coatings. Nonetheless, the study demonstrates how easily some tungsten particles dissolve under ambient conditions. Dissolution/desorption batch experiments with contaminated soil show the rate of tungsten loss is further complicated when tungsten metal is introduced

to the soil. However, the rate of tungsten dissolution/desorption in soil is rapid. Given additional variables of interaction of tungsten with soil and the short duration of these experiments, extrapolation of tungsten particle persistence in soil is not possible.

4.4 Task 5 - Sorption and desorption laboratory studies

The purpose of sorption/desorption experiments was to measure the equilibrium distribution coefficient (K_d) for tungsten in order to predict the amount of tungsten that adsorbed to the soil matrix. K_d is used in computer models to assess the transport of tungsten through the soil matrix.

Desorption experiments are used to assess whether sorption is a linear and reversible reaction. If sorption is reversible, derived distribution coefficients from the sorption tests can be used to predict how rapidly tungsten desorbs from the soil over time. Instead of starting with clean soil and contaminated water, sorption experiments use clean soil and contaminated water, and desorption experiments use clean water and contaminated soil, as tungsten moves from the soil to the water during the incubation period. As with sorption experiments, if appropriate concentration measurements and mass balances are performed, a K_d value can be estimated from the data. If sorption is reversible, K_d values determined in the sorption and desorption experiments are identical. If sorption is not completely reversible, the desorption K_d value will be larger than the sorption value. The difference between the two values provides the degree of irreversible sorption (or very slow desorption).

4.4.1 Batch experiments

In general, the batch experiments were conducted following American Society of Testing Methods (ASTM) Method D4646 (ASTM 2008). However, the first set of experiments focused on assessing the change in K_d over time, and thus experiments were not limited to a 24-hr interval as specified in the ASTM methodology.

4.4.1.1 Effect of time on sorption partitioning coefficients

In a previous study, sorptive K_d for tungsten was measured on 18 soils (sodium tungstate initial-spiking solution) over several time intervals to 120 days (Larson 2008, personal communication). For 12 of the 18 soils, significant (up to ~700 times larger) increases in the sorptive K_d were noted

with time (to 120 days). These large K_d changes over time could be a consequence of physical factors, such as diffusion in the tortuous media or intercalation within smectitic clays. Changes in soil and soil solution geochemical parameters because of redox reactions are the more likely cause of K_d changes over time. According to Bednar et al. (2008), dissolved tungsten changes its speciation with time, forming less mobile species, and soil redox potential is decreased as tungsten dissolves. Linked to the latter phenomena are the redox status and pH of soils and their effect on both the speciation of tungsten and hydrous oxides of iron and manganese. Previous work using a variety of soil types and contaminants demonstrated a significant role of hydrous oxides for assessing migration of oxyanions similar to tungsten, such as arsenic, selenium, chromium, and vanadium (Jenne 1968; Korte et al. 1976).

The results presented below describe measurements of K_d for soils from Camp Edwards and address whether K_d changes as a function of time. Each experiment was performed in triplicate using DI spiked with sodium tungstate. The aqueous tungsten concentrations were fitted to the linear Freundlich isotherm model for calculation of partition coefficients using four different concentrations (0.1, 1,100, and 1,000 mg/kg).

Table 10. Grain size distribution of Camp Edwards soils used for partition coefficient determinations.

Sample ID	% Sand	% Silt	% Clay	Soil Classification
Soil 1 MMR-A1	77	7	16	Sandy Loam
Soil 2 MMR-A2	85	4	11	Sandy Loam
Soil 3 MMR-J1	93	1	6	Sand
Soil 4 MMR-J2	89	6	5	Sand
Soil 5 MMR-T1	58	19	23	Sandy Clay Loam
Soil 6 MMR-T2	74	8	18	Sandy Loam

Six soils, including three sandy loams, two sands, and one sandy clay loam were used for the tungstate sorption K_d determinations (Table 10). The soils contained no tungsten from SAR firing, nor were they treated with Maectite — a proprietary phosphate-based agent used to stabilize lead in the SAR berm soils at Camp Edwards. The samples were collected in presumed background locations at the A, J, and T Ranges. Each sample consisted of a 50-increment surface sample collected from 0 to 2.5 cm over a random area. A presumption was that this approach would yield a soil sample largely representative of the entire range.

Twelve g of air-dried homogenized soil were weighed and placed into 125-mL high-density polyethylene bottles. Each bottle was filled with 120 mL of DI containing dissolved tungsten (as sodium tungstate), nominally at 0, 10, 20, 50, and 100 mg/L; and each concentration was spiked in triplicate for a total of 15 bottles. The zero-spike level was used to determine if any natural tungsten was present in the soil; since no tungsten was detected in the zero spike level samples, these were indeed background samples.

The bottles were agitated on a reciprocating shaker throughout the experiment. Half-ml aliquots were collected and filtered at 1-, 30-, 60-, 90-, 120-, and 180-day intervals for K_d determinations. All samples were analyzed on a Perkin Elmer Elan DRC II ICP-MS. The aliquots were diluted as appropriate for ICP-MS analysis (20 to 1,000 times dilution factors), according to standard methods developed at ERDC-EL, and using Terbium-159 and Holmium-165 as internal standards. Second- and third-source tungsten check standards were also analyzed with each analytical batch to verify instrumental accuracy. Sample analysis followed the procedures outlined in Clausen et al. (2007b).

Concentration data (Table 11; Appendix D) were plotted on a logarithmic scale to determine K_d by using the linear Freundlich isotherm model (Langmuir 1997) in which K_d values are calculated as the antilog of the intercept of the linear regression line. Use of the linear model was supported for this study because the correlation coefficients (r^2) for most soils and time intervals were greater than 0.90. Two of the soils, however, have limited sorption capacity for tungsten and had correlation coefficients of 0.7 or less, suggesting the highest spike value was large enough to result in non-linear sorption.

At completion of the 180-day experiment, a final aliquot was collected from the 10 mg/L spike samples and analyzed by HPLC-ICP-MS for tungsten speciation, following a modification of the method of Bednar et al. (2007). An Agilent 1100-HPLC equipped with a Shodex KW-803 size exclusion column was interfaced to the Perkin Elmer Elan DRC II to determine tungsten speciation by size. This analysis indicated that some polytungstates formed in the sorption experiment solutions during the 180-day experiments.

Previous work by Bednar et al. (2008) suggests that these speciation changes will affect sorption of tungsten to soils, and polytungstates will have a larger K_d.

A plot of tungsten K_d versus time for these six soils indicates an increase from 30 to 60 days for four of the soils and a stabilization of K_d thereafter (Fig. 12). The other two soil K_d values continued to increase until 120 days; measured values remained similar or decreased slightly thereafter.

These results can be compared with those obtained by Larson (personal communication, 2007) on soils classified as sandy silt from Camp Edwards. Larson reported a maximum result of ~ 90 mL/g after approximately 40 to 50 days. Larson's data compare well to the time required to achieve a steady state in this study, although the K_d results for coarser soil in this study were approximately three times greater. Larson used soil with a pH of 4.9. Using a silty loam soil, Bednar et al. (2008) reported a K_d of 141 mL/g at pH 7, which is in the same range reported in this study.

Table 11. Tungsten sorption soil partition coefficients in batch studies at six elapsed times.

	Sorption Partition Coefficient K_d (L/kg) *					
Time (days)	Soil 1 MMR-A1	Soil 2 MMR-A2	Soil 3 MMR-J1	Soil 4 MMR-J2	Soil 5 MMR-T1	Soil 6 MMR-T2

	110	168	241	134	337	361

*Raw data are presented in Appendix D.

Results suggest the standard 24-hr batch sorption test protocol, as defined by ASTM, is inappropriate for determining tungsten K_ds. Use of the ASTM method will result in under prediction of the degree of tungsten sorption and ultimately will over predict the rate of movement.

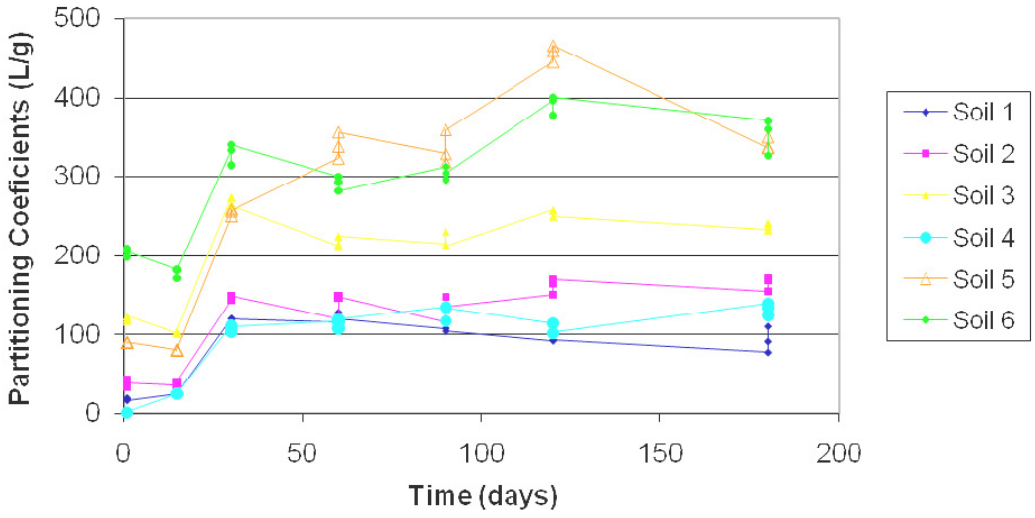

Figure 12. Tungsten sorption partition coefficients from soil batch tests.

4.4.1.2 Effect of different substrates on tungsten sorption/desorption

Brief laboratory batch experiments were performed to examine the relative ability of several materials to sorb and desorb tungsten. Experimental conditions were not controlled with respect to pH and redox potential, and the experimental time frame was brief, i.e. 24 hr. Hence, the results can only be considered preliminary.

In the experiment sorption phase, 4.5 g of material was added to a 4-oz amber glass container. This material was spiked with a 70-ml solution containing 10 mg/L sodium tungstate. Samples were equilibrated for 24 hr on an orbital shaker table at 100 rpm. After 24 hr the test samples were allowed to settle for 2 hr, and the aqueous solution pipetted off, placed into a 100-ml plastic container and chilled prior to analysis. After the leachate was removed, the material was allowed to air dry.

The same soil used in the sorption phase of the test was spiked with 70 ml of DI, which was added to 4.5 g of soil. Samples were equilibrated for 24 hrs on an orbital shaker table at 100 rpm. After 24 hr, test samples were allowed to settle for 2 hr; the aqueous solution was pipetted off, placed into a 100-ml plastic container, and chilled prior to analysis.

Three pure materials were tested: aluminum oxide (Linde "A" polish, a pure grade), goethite, and kaolinite. Specific attributes of these materials were not measured except for their efficiency in sorbing tungsten. For kaolinite, individual sources can yield significant variation in physical properties. Nonetheless, aluminum oxide was expected to be the better sorbent because this material has a zero point charge close to a pH of 8 (Schulthess and Sparks 1987). Because the surface charge on aluminum oxide (and goethite) becomes more positive with increasing acidity, the lower the pH, the more easily the tungstate anion is retained. Based solely on charge considerations, goethite, with a zero point of charge near neutral and a less steep increase in positive charge with increasing acidity (Langmuir 1997), should be less effective than aluminum oxide. Although recent work (Schroth and Sposito 1997) has reported a zero point charge between pH 5 and 6 for kaolinite, the literature includes many pH values in the range of 3 to 4. Consequently, this single-layer clay may have a significant negative charge at low pH (Langmuir 1997) and may not be an effective sorbent for tungstate under acidic conditions.

These pure materials were compared to three soils: Ottawa Sand, a forest soil from Camp Edwards (selected because visual inspection indicated a greater than typical organic matter content for site soils), and a sample designated as MMRBMB022S1. The latter soil was a contaminated SAR soil containing 1,530 mg/kg of tungsten obtained from the middle berm area on Bravo Range. Because the MMRBMB022S1 sample was obtained from the SAR, it is presumed to contain both metallic tungsten and tungsten sorbed to the soil surface. Although MMRBMB022S1 soil was spiked with sodium tungstate, the presence of anthropogenic metallic tungsten suggested the desorption test also includes a dissolution component; this is unlike the other materials tested that have only a desorption component Therefore, the results for the MMRBMB022S1 sample represent both desorption and dissolution processes.

As expected, aluminum oxide was the most sorptive material and was two orders of magnitude more efficient than Camp Edwards forest soil, which is the second highest sorptive material (Appendix E). Pure Ottawa Sand was approximately half as effective as soil from the forest area. MMRBMB022S1 was almost as effective as Ottawa Sand, although any evaluation of MMRBMB022S1 must be tempered with awareness that this soil was already highly contaminated with metallic tungsten from firing activities, with a portion of the tungsten previously dissolved and sorbed to

the soil surface. Pure Kaolinite and Goethite were approximately equal in their effectiveness, with both being half as effective as the soils from Camp Edwards. Desorption experiments showed that tested materials released tungsten in the same relative order as during sorption. The desorption data, however, indicated less release of the sorbed tungsten, indicating that over the 24-hr-experimental time frame, tungsten sorption is not fully reversible. The authors' previous work with similar anions such as TCO_4^- (Clausen et al. 1997; Gu et al. 1994, 1996; Clausen and Early 2002) and PO_4^- (David et al. 2004; AMEC 2002) that behave similarly to WO_4^- suggests that an experiment of longer duration might reveal that tungsten is fully reversible. In summary, relative effectiveness for sorption/desorption (from greatest to least) was: Al_2O_3, forest soil, Ottawa Sand, MMRBMB022S1, Kaolinite, Goethite.

These results suggest that earlier batch dissolution/desorption tests, previously discussed in Section 4.3.3, primarily contained tungsten metal. In current experiments where soil was spiked with sodium tungstate and desorbed with DI, a low rate of tungsten removal resulted. However, a high percentage of tungsten was observed in the leachate batch dissolution/desorption tests, suggesting that a greater proportion of tungsten metal versus tungstate sorbed to the soil surface was present in contaminated SAR soils.

Xu et al. (2006) present evidence that phosphate either forms more soluble complexes with tungsten or competes for sorption sites, thereby increasing rather than hindering tungsten's mobility. In contrast, phosphate complexes inhibit the mobility of lead. A number of preliminary experiments performed with contaminated soil MMRBMB022S1 showed that when phosphate was added, less sorption occurred; however, the effect was only a few percent. No discernable effect of adding phosphate on desorption was detected. Any conclusions from these data must be tempered with unknown effects of the previous presence of tungsten and the small number of experiments conducted. The percentage of phosphate in the Maectite material used to treat the SAR is unknown, because the Maectite is proprietary material. Nevertheless, when phosphate is added, the remaining tungsten dissolves and sorption may be inhibited for the SAR ranges at Camp Edwards. Conversely, dissolved and subsequently sorbed tungsten may not be affected.

4.4.2 Column testing

Three column experiments were conducted as part of Task 5; two assessed dissolution/desorption of tungsten from a contaminated soil, and a third assessed sorption/desorption/dissolution of aqueous sodium tungstate (Table 12). These tests were conducted to determine how much leachate was generated from a SAR-contaminated soil from either desorption or dissolution processes. Our secondary objective was to determine the proportional difference of the two transport process from the previous batch experiments where each mechanism was studied independently, as described in Section 4.3.

Prior to conducting the experiments, permeability of the columns was determined with a falling-head test. In addition, a chloride tracer test confirmed the uniformity of the column packing and the absence of significant channeling.

Table 12. Treatment conditions in column experiments.

Column ID	Treatment Conditions	Cumulative Time (hrs)	Cumulative Pore Volumes	Cumulative Volume (L)
1	Desorption/dissolution of tungsten	451	39	8.1
2	Sorption of sodium tungstate and desorption/dissolution of tungsten and sodium tungstate	124	10.8	2.2
3	Desorption/dissolution of tungsten	50	4.4	4.4

Each of the three columns was prepared in an identical fashion (Figure 13), using a 61-cm-long glass chromatography column with a 5.0-cm inner diameter made by Ace Glass, Inc. (Catalog #5889-40). The column had a 1-cm permeable glass frit at the base. Above the frit was 2 cm of glass wool and 3 cm (70 g) of 5-mm glass beads, pre-washed with DI, which prevented sediment from clogging the frit. Each column was rinsed several times with DI prior to loading with soil. The columns were dry packed with a 20-cm layer (504 g) of soil. DI was added, and the soil was tamped slightly to eliminate voids.

The gravelly sand soils used in the tests were obtained from Kilo (K) Range at Camp Edwards and were originally designated K6 and K7. When collected, soils had a pH of 7.2 and a moisture content of approximately 20%. The tungsten content of the K6 and K7 soils was 28 and 52 mg/kg, respectively. Differentiation between the metallic species present and the sorbed species of the various metals in the soil was not possible. The remaining

chemical analyses showed the soils (K6/K7): to be very similar: organic carbon content 2.2/2.7%; bulk density 1.3/1.2 g/cm^3; cation exchange capacity 16/17 meq/g; aluminum 7260/7,550 mg/kg; barium 22/22 mg/kg; beryllium 0.33/0.33 mg/kg; calcium 15,900/15,400 mg/kg; chromium 600/600 mg/kg; copper 390/240 mg/kg; iron 13,300/13,300 mg/kg; potassium 1,100/1,100 mg/kg; magnesium 1,300/1,480 mg/kg; manganese 120/120 mg/kg; sodium 130/120 mg/kg; nickel 10/9 mg/kg; lead 640/700 mg/kg; vanadium 18/20 mg/kg; and zinc 64/38 mg/kg. The following metals were not detected above the reporting limit: silver, arsenic, cadmium, antimony, and selenium. K7 soil was used in Columns 1 and 2, and a 50:50 mixture of K7 and K6 soil was used in Column 3. The 50:50 mixture was used because there was insufficient K7 material to pack Column 3.

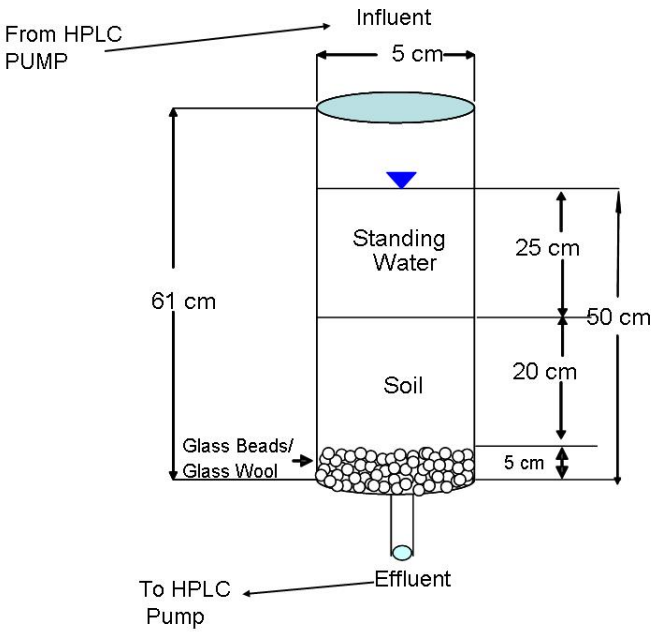

Figure 13. Column design for the study.

A 25-cm head of water was maintained on top of the soil surface. Manual flow control using a stopcock was not effective. Flow was thus controlled by an 8-channel multi-head Cole–Palmer Masterflex L/S HPLC peristaltic pump, Model 7519-06. The flow rate for all columns was 0.3 mL/min, except for Column 3; which used a second Cole–Palmer Masterflex L/S HPLC peristaltic pump, Model 7519-06, at 0.6 ml/min. All columns were wrapped in aluminum foil. The laboratory had no exterior windows and was generally dark except when samples were collected.

Two fraction collectors, either an ISCO Retriever II, Model 69-283-047 or a Spectra-Chrom, Model CF-1, were used when collecting samples at a high frequency. When a high sample frequency was not needed, samples were collected manually.

To determine residence time of one pore volume, the soil volume and soil porosity must be calculated. Soil volume in each column was found to be 392.5 cm^3 by using the equation:

$$V_{soil} = \pi * r^2 * h \qquad eq.\ 1\}$$

where:

V_{soil} = volume of soil in the column (cm^3)
π = pi (3.1416)
r = radius of the column (2.5 cm)
h = thickness of soil in the column (20 cm).

The porosity of the soil can be calculated using:

$$n = 1 - (\rho_b / \rho_s) \qquad eq.\ 2\}$$

where:

n = porosity of the soil (unit less)
ρ_b = bulk density of the soil (1.26 g/cm^3)
ρ_s = specific gravity of the soil (2.65 g/cm^3).

The calculated porosity of the soil is 0.52. Because columns typically cannot be compacted as well as field soil, the porosity of a column experiment is usually higher than a field value. Hence, the value of 52% is higher than for coarse soils at Camp Edwards. The pore volume (P_v) of the soil is the volume of soil (V_{soil}) times porosity (n), which yields a value of 205.9 cm^3. The residence time of one pore volume is then calculated using:

$$R_T = (P_v / Q) \qquad eq.\ 3\}$$

where:

R_T = residence time of one pore volume (s)
P_v = pore-volume (205.9 cm^3)
Q = flow rate through the column (0.3 mL/min or 0.005 mL/s).

Solving for R_T in equation 3 yields a residence time of one pore volume in the column of 4.12E+4 s or 11.4 hr.

At column start up, a solution of sodium chloride was added, and the chloride acted as tracer for assessment of flow conditions. The salt solution had a chloride concentration of 50 mg/L.

4.4.2.1 Falling-head test

A falling-head permeameter test was conducted on each column to assess the hydraulic conductivity of the soil. The test allows unimpeded flow from the column and measures the change in head over a specified time period. The equation to calculate the hydraulic conductivity is:

$$K = (L * d^2) / (D^2 * t) * ln \blacktriangle h \qquad \text{eq. 4}\}$$

where:

K = hydraulic conductivity (cm/s)
L = length of the soil sample (20 cm)
d^2 and D^2 = diameter of column (5 cm)
t = time (s)
$\blacktriangle h$ = change in height of water column (cm).

The calculated hydraulic conductivity (Table 13, uncorrected) has to be corrected for changes in viscosity as a function of temperature. The soil temperature was approximately 17°C, equating to a correction factor of 1.077, which is based on values reported by Kasenow (2006). The results indicate hydraulic conductivity varied from 5.04 x 10^{-3} cm/s for Column 1 to 2.69 x 10^{-2} cm/s for Column 2, which is a reflection of packing consistency. Some variation in hydraulic conductivity may exist due to differential settling as material was transferred from sample bags to the columns.

Table 13. Falling-head permeameter hydraulic conductivity determinations.

Column	Change in Water Column height- ▲h (cm)	Time (s)	Uncorrected Hydraulic Conductivity (cm/s)	Corrected Hydraulic Conductivity (cm/s)
1	5.4	7,200	4.68 x 10^{-3}	5.04 x 10^{-3}
2	3.2	900	2.58 x 10^{-2}	2.69 x 10^{-2}
3	6.5	1,800	2.08 x 10^{-2}	2.24 x 10^{-2}

Using information from the current SESOIL model for MMR (Kulbersh; CENAE personal communication), the calculated vertical hydraulic conductivity of the Camp Edwards soil is approximately 3.12E-5 cm/s over the entire 36 m (120 ft) thickness of the unsaturated zone. The depositional lithologic history at Camp Edwards consists of a coarsening upwards sequence. Therefore, soils at or near the surface are expected to have a higher hydraulic conductivity than the average. Additionally, packing the soils in a column as tightly as they occur in nature is nearly impossible, and thus the column conductivity is likely to be higher than for field measurements. Consequently, the measured hydraulic conductivity values for the column experiments are reasonable.

4.4.2.2 Tracer experiments

At the start of each column experiment, a tracer test was conducted. Tracer data can be found in Appendix F. Tracer tests were conducted with a conservative trace, chloride, to assess whether the breakthrough curves exhibited plug-type flow, where the tracer concentration has a nearly vertical rise indicative of an advective, dispersive front. The concentration should then plateau near the influent value, and when the tracer is discontinued from the influent, the decline should be almost vertical.

The chloride breakthrough curve for Column 1 shows a more gradual rate of chloride breakthrough, as well as some shouldering instead of a plateau (Figure 14). Most likely, these data are the result of non-uniform pore water velocity rather than sorption of the chloride onto the soil. Non-uniform pore water velocity was probably caused by heterogeneity in the column packing. Column 1 chloride levels reached a plateau near the influent concentration of 50 mg/L in less than 2 days. At approximately 55 hr, the chloride input was discontinued, and the remaining chloride was flushed out within 50 hr or approximately five pore volumes.

The chloride breakthrough curves for Columns 2 and 3 are shown in Figure 15. The Column 3 curve is similar to Column 1. In both columns, the chloride concentration declined rapidly when input was discontinued.

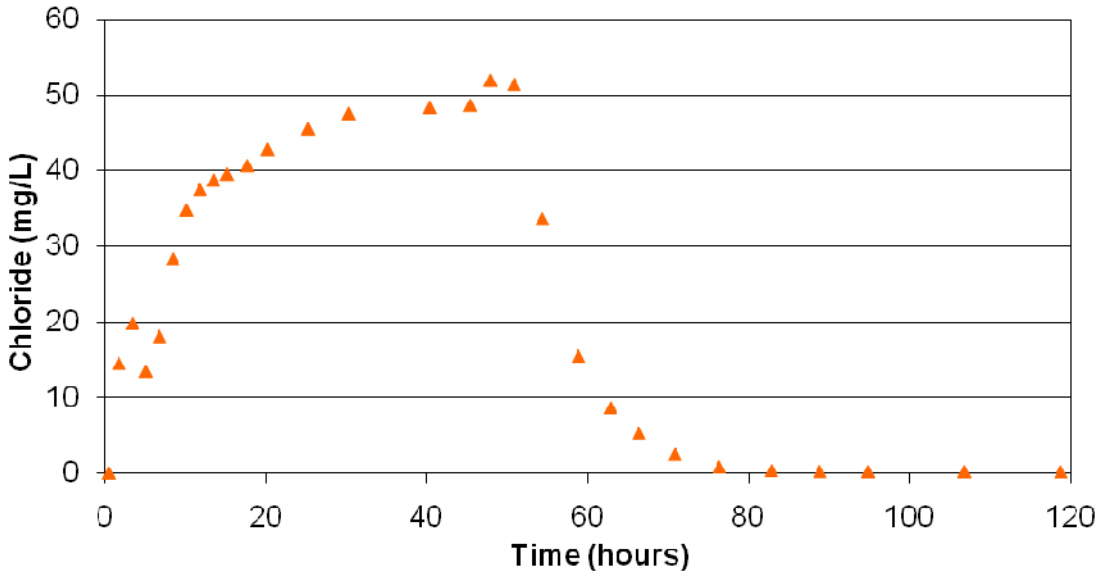

Figure 14. Chloride breakthrough curve for Column 1. Soil concentration is 52 mg/kg tungsten. (Raw data presented in Appendix F).

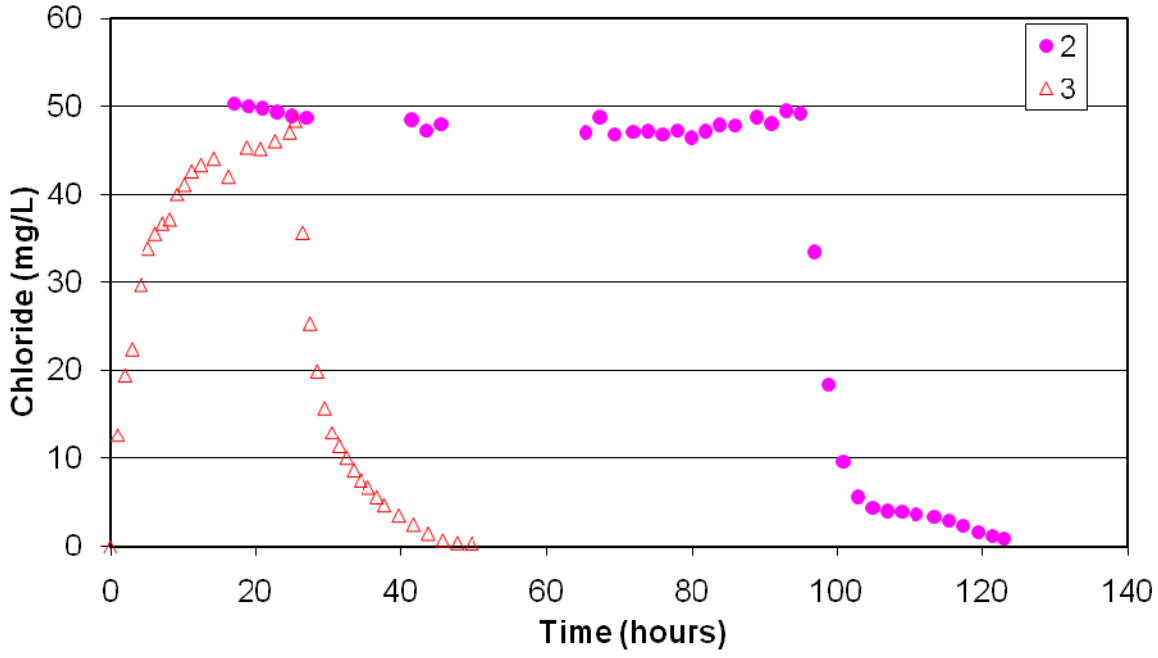

Figure 15. Chloride breakthrough curves for Columns 2 (purple) and 3 (red). (Raw data presented in Appendix F).

4.4.2.3 Leaching experiments

In the Column 1 experiment, soil collected in the field contained 52 mg/kg of tungsten and was leached with 40 pore volumes of DI as previously described. Because soil was obtained from the SAR and exposed to weathering processes, both metallic and sorptive species of tungsten were possibly present. Therefore, leachate generated in this experiment is due to both dissolution and desorption processes. The tungsten concentration in the effluent was initially greater than 0.5 mg/L but quickly leveled off to near 0.15 mg/L (Figure 16; Appendix F). The breakthough was so rapid in all three column tests that initial breakthrough was not captured. Observed leachate concentrations, however, are lower than those obtained from the batch tests (Section 4.3.3) with low tungsten soil levels. If we assume that the release rate of tungsten in the batch experiments is similar to that of the columns, the likely explanation is that greater soil surface area in the columns results in greater re-adsorption of the tungsten intially desorbed from the soil. Equilibrium between the desorption of tungsten from soil into the water appears to occur at approximately five pore volumes.

The Column 2 experiment used the same soil as in Column 1 (52 mg/kg of field-contaminated tungsten). In this case, the influent had a concentration of 10 mg/L sodium tungstate (Figure 17). The concentration in the effluent was relatively stable and remained between approximately 0.3 mg/L and slightly more than 0.4 mg/L. The leachate is the result of both dissolution and dissolution of the tungsten introduced from SAR firing, as well as a lack of desorption or possible sorption and subsequent desorption of the added sodium tungstate. Fluctuations are believed to be partly a result of vascilating flow rates and column pressures. The data demonstrated more than 95% removal of the influent tungsten with no indication that the removal rate changed over the course of the experiment. A decrease in removal rate, i.e higher concentrations, would suggest exhaustion of the sorption sites. These results suggest that soil retains a fairly large capacity to remove tungstate ions through sorption processes. Because of oscillation in leachate concentrations, determination of actual equilibrium achievement times was difficult but appeared to be similar to Column 1 and occured around five pore volumes.

The Column 3 experiment was performed in the same manner as Column 1 in which contaminated soil (a 50:50 mixture of the 52 mg/kg soil and 28 mg/kg soil collected in an adjacent location) was leached with DI. In this case the flow rate was twice as rapid (Figure 18). Concentrations were higher than those at the lower flow rate and varied between approximately

0.4 and 0.6 mg/L. These concentrations were somewhat more than double those of the slower flow rate experiment, suggesting that the degree of sorption as compared to Column 1 was half as much.

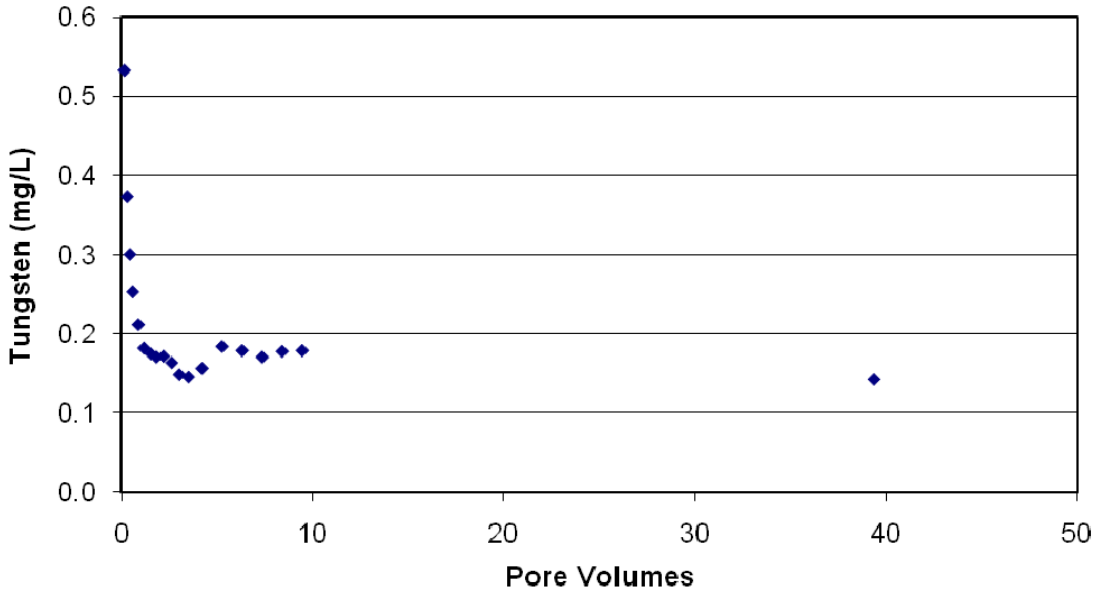

Figure 16. Desorption of tungsten from soil contaminated at 52 mg/kg (Column 1). (Raw data presented in Appendix F).

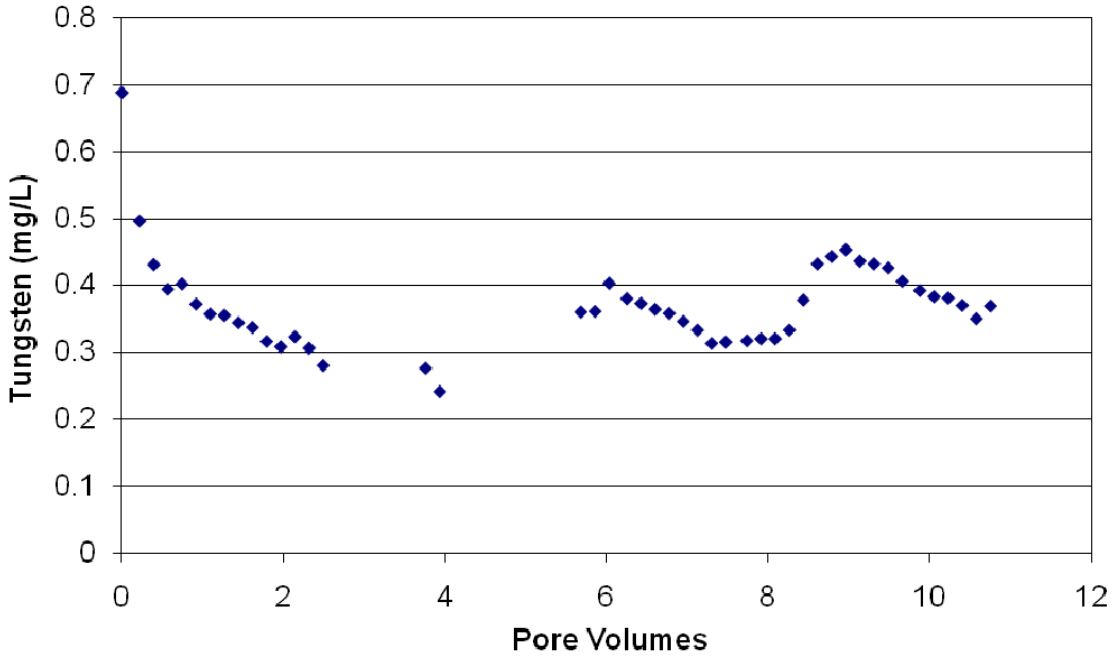

Figure 17. Tungsten in effluent when soil contaminated with 52 mg/kg of tungsten is leached with 10mg/L sodium tungstate (Column 2). (Raw data presented in Appendix F).

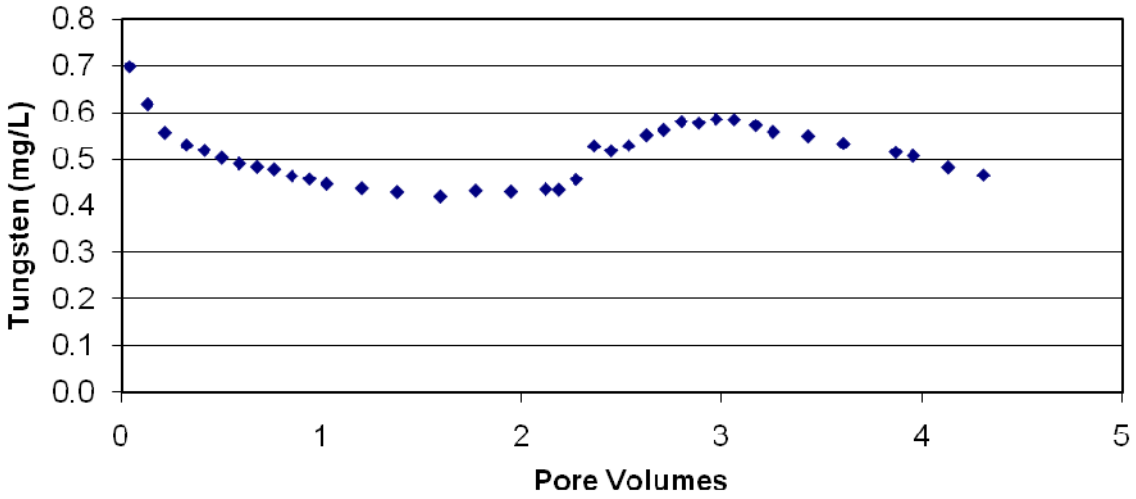

Figure 18. Contaminated soil (50:50 mixture of 52 mg/kg and 28 mg/kg tungsten) leached with DI (Column 3) at ~twice the flow rate of Column 1 experiment. (Raw data presented in Appendix F.)

Reasons why concentrations are higher at a faster flow rate are open to speculation. Batch test data indicated that desorption occurred to a lesser extent than sorption, but such data do not shed light on the reaction rate. Possibly, some tungsten dissolves/desorbs rapidly, and with the faster flow rate, has a lesser opportunity to re-adsorb and is transmitted through the column. Additional and longer experiments would be required to determine the mechanisms with certainty. The implications for Camp Edwards are that high intensity precipitation events likely result in rapid flux of water through the vadose zone, which in turn results in more rapid dissolution of metallic tungsten and desorption of tungsten oxides from the soil surface. When tungsten is mobilized as tungstate, under high-infiltration rate conditions it is re-adsorbed less efficiently. Consequently, tungstate is rapidly transmitted through the vadose zone to the water table. Under low-intensity precipitation, dissolution and desorption of tungsten is likely decreased, and the slower rate of transport through the vadose zone allows for a higher degree of re-adsorption, limiting the amount of tungstate that reaches groundwater.

4.5 Task 6 – Unsaturated zone flow modeling

Task 6 consisted of unsaturated zone modeling and used information from Tasks 1 through 5 in order to predict the tungsten transport rate across the approximate 36-m unsaturated zone at Camp Edwards. ERDC-CRREL performed this task using the Seasonal Soil Compartment (SESOIL) model (Bonazountas and Wagner 1984; Hetrick et al. 1993) and the same input

parameters used for previous unsaturated modeling efforts at Camp Edwards to support IAGWSP (Appendix G).

As noted in Section 4.4.1.1, tungsten K_d values measured in Task 5 ranged from a low of approximately 2o L/kg to a high of approximately 450 L/kg; K_d increased with contact time up to approximately 60 days or more. The initial modeling step was to predict whether tungsten detected in the soil samples at SARs would impact groundwater. Tungsten predicted to reach groundwater was modeled using the Analytical Transient 1-, 2-, and 3-Dimensional Simulation of Waste Transport in the Aquifer System (AT123D; Yeh 1981) to calculate the concentration in the groundwater. Both models were run using the SEVIEW software program (version 6.3, Environmental Software Consultants 2006). SESOIL was used to predict the time required for migration through the vadose zone, and the AT123D model was used to predict the groundwater concentration at the interface of the unsaturated and saturated zones. Saturated zone modeling is discussed in the next subsection, and the models are explained in more detail in Appendix G.

4.5.1 Unsaturated zone modeling results

With a tungsten soil concentration of 70 mg/kg and a K_d of 200 L/kg, the SESOIL model predicted tungsten would not migrate more than 1 m below the ground surface (bgs). Increasing the soil concentration to 700 and 7,000 mg/kg had no impact on the predicted depth of migration. Clearly, these simulations seriously underestimated the actual extent of tungsten migration as shown by the sampling of lysimeters and MW-72S on B Range. In order to simulate additional transport, 20 L/g, the lowest K_d measured in these experiments, was used with an initial soil concentration at 70 mg/kg. This simulation did predict tungsten would reach groundwater, albeit in 700 years. The maximum concentration predicted was 30 µg/L. Changing the source-term concentration changed the concentration predicted in groundwater but did not change the transport time. Thus, even with the lowest K_d measured in this study, the modeling results seriously under predict what was observed in the field.

To better understand why the modeling under predicts tungsten migration, SESOIL simulation was conducted with a K_d of 1 L/kg, using an initial soil concentration of 70 mg/kg. In this scenario, tungsten reaches the groundwater in 25 years as compared to 6 years. Even with a K_d of 1 L/kg, 50 years were required before groundwater concentration reached a maximum level of 957 µg/L, whereas the maximum tungsten concentration observed at MW-72S was approximately 550 µg/L. These results sug-

gest the tungsten observed at MW-72S resulted from a source area having an average soil concentration greater than 70 mg/kg. As noted in Clausen et al. (2007b), tungsten soil concentrations in the berm surface soils at B Range, where MW-72S is located, were 100 to 1,000 mg/kg.

A possible reason that unsaturated zone modeling results are at odds with field observations is that tungsten migration is a more complex phenomena than can be simulated with SESOIL. As observed in the batch experiments (Section 4.3), the degree of tungsten sorption is variable and dependent upon the contact time with the surrounding soil. If infiltration rates are lower, there is a greater degree of tungsten adsorption. As infiltration rates are increased, the efficiency of adsorption decreases. SESOIL can not accommodate variable infiltration rates or K_d values and does not account for desorption of tungsten from the soil surface and subsequent remobilization. Further column testing would be needed to assess the resulting difference in dissolution and desorption/sorption rates as a function of infiltration rates. Column testing in Section 4.4 suggests higher flow rates result in greater mass of transported tungsten, which would also correspond with a lower associated K_d.

More importantly, SESOIL assumes the initial release of a contaminant is in a dissolved phase and does not account for dissolution. The SESOIL process of releasing a soil concentration into solution is dependent upon solubility. Although, the solubility of metallic tungsten is unknown, results from field lysimeters (Clausen et al. 2007b) suggest it is at least 400 mg/L. Consequently, SESOIL will allow conversion of a large mass of tungsten to a solute form. However, the amount of tungsten released in solution is going to be a function of precipitation intensity, humidity levels, pH of the precipitation.

Additionally, SESOIL does not account for competitive sorption. At B, C and I Ranges, Maectite, a phosphate-based agent, was used to fix lead in the soil prior to the use of tungsten ammunition. The soil sorption sites, therefore, were loaded with phosphate, which can compete with tungstate (Xu et al. 2006). As a consequence, when tungsten rounds began to be used in training, a limited number of sorption sites were possibly available in the surface soil. In effect, the presence of Maectite lowered the tungsten K_d.

Of serious concern, SESOIL usage is unable to account for the extent of variation in geochemical and hydraulic conditions. The migration of tungsten through the Camp Edwards vadose zone is apparently dependent on several factors that are not easily accommodated by a modeling approach

with strict reliance on K_ds. The extent that conditions change with soil depth is probably greater than can be addressed with the model. For example, sequences of gravel and cobbles have been reported in the vadose zone (AMEC 2001a). In such locations, water flow is probably so rapid and the substrate surface area is so low that little opportunity exists for attenuation regardless of pH. If these coarse sequences occurred in locations where tungsten was migrating, the average hydraulic conditions, as used in the model, would under predict the flow rate of pore water.

Analogous to other metals that migrate chiefly as oxyanions (e.g. molybdenum and vanadium), tungsten is more mobile under oxidizing conditions. Measurement or simulation of redox conditions as they occur in the field is difficult. Closed vials and columns used to measure K_d probably do not mimic the subsurface and may actually become more reducing over time. The extent to which redox conditions affect tungsten mobility has not been measured and was not addressed in the model simulations. The subsurface redox conditions at Camp Edwards have been documented in numerous ways, including direct measurements of dissolved oxygen and indirect observations such as the lack of detections of reduced species (AMEC 2001a, 2001b). As observed at Camp Edwards, sandy soil, combined with high rainfall and rapid movement through the vadose zone, are conducive to the maintenance of oxidizing conditions. As with variation in soil texture, the redox environment is not uniform throughout the vadose zone (AMEC 2001a, 2001b).

Finally, tungsten speciation changes with time and geochemical conditions (Bednar et al. 2008). Although polytungstates and tungstate are negatively charged, they are much larger ions and this may decrease their availability to certain sorption sites. For these reasons, SESOIL modeling based on a laboratory-derived K_d and on average hydraulic and geochemical conditions is apparently unreliable for the prediction of tungsten mobility at Camp Edwards.

4.6 Task 7 – Saturated zone particle tracking

Paths of ground water originating as recharge at B Range were simulated with the existing USGS regional ground-water flow model developed for MMR using particle tracking. Particle paths were delineated in map view (Figure 19). The original intent was to develop detailed particle tracks for all SARs, with the anticipation that tungsten would likely be present at all ranges where the tungsten/nylon project was used. However, lack of tungsten in groundwater at C and SE/SW Ranges, and lack of an extensive area of contamination at B Range, made detailed particle tracking unnecessary.

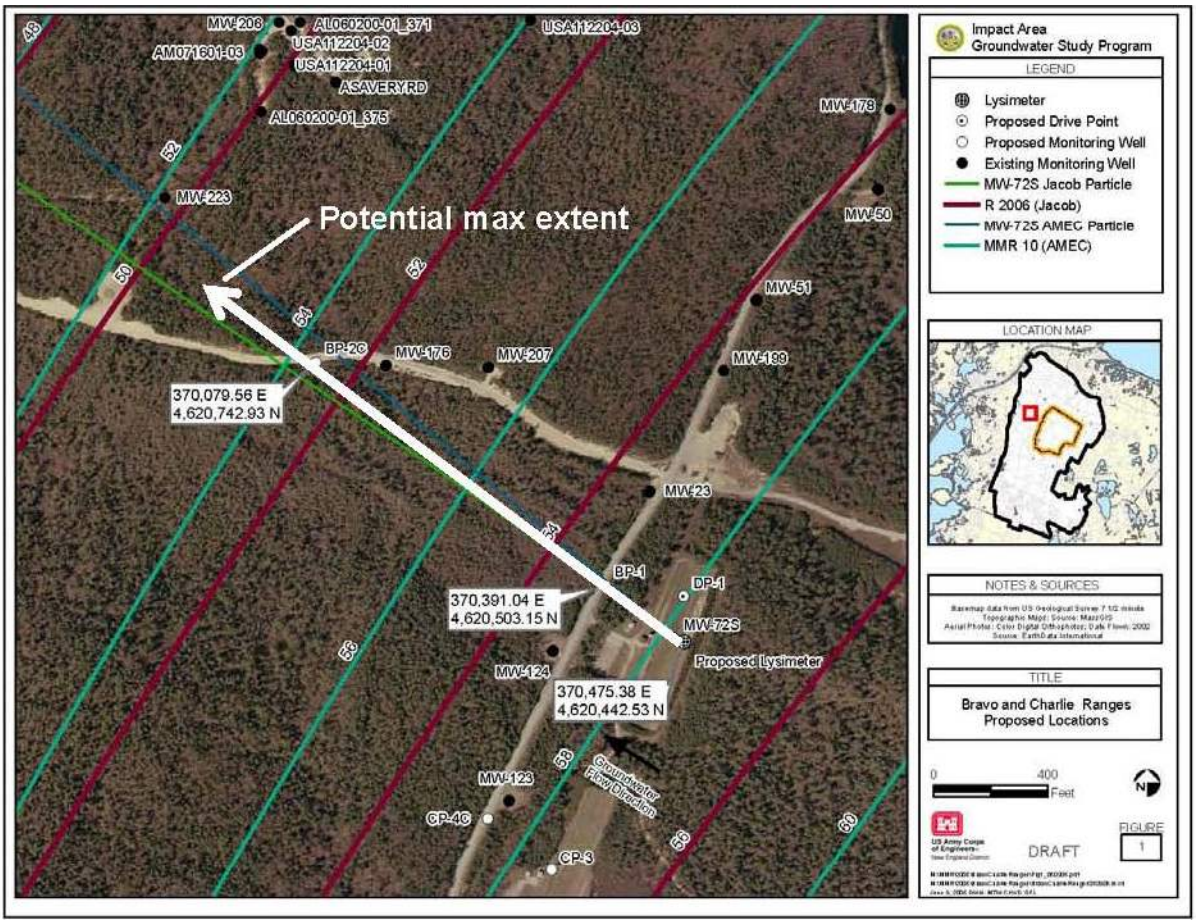

Figure 19. Particle track originating at Bravo Range.

Particle tracks were generated beginning at all SARs where tungsten projectiles were used (Figure 20) in the event that tungsten was identified at the other SAR not studied as part of this activity. These particle tracks represent the general migration path of a contaminant released at the SAR. However, because most ranges had no identifiable zone of tungsten contamination in groundwater, the release pattern is a periodic pulse. Searching for potential contamination, if it exists, would likely fail and be very expensive. Owing to the short period of time (< 6 years) that tungsten projectiles were used, the maximum extent of tungsten in groundwater downgradient can be estimated. The groundwater flow velocity is roughly 0.3m/day (1 ft/day) (AMEC 2001a), yielding a maximum horizontal distance of 2,190 ft. However, as noted in Section 4, the soils at Camp Edwards have a high capacity to adsorb tungsten. Therefore, any tungsten reaching groundwater is likely to be attenuated near the source term, thus limiting its lateral movement in the aquifer. This premise is supported by the drive-point and monitoring wells results for B, C, and SE/SW Ranges, which showed no detectable downgradient presence of tungsten.

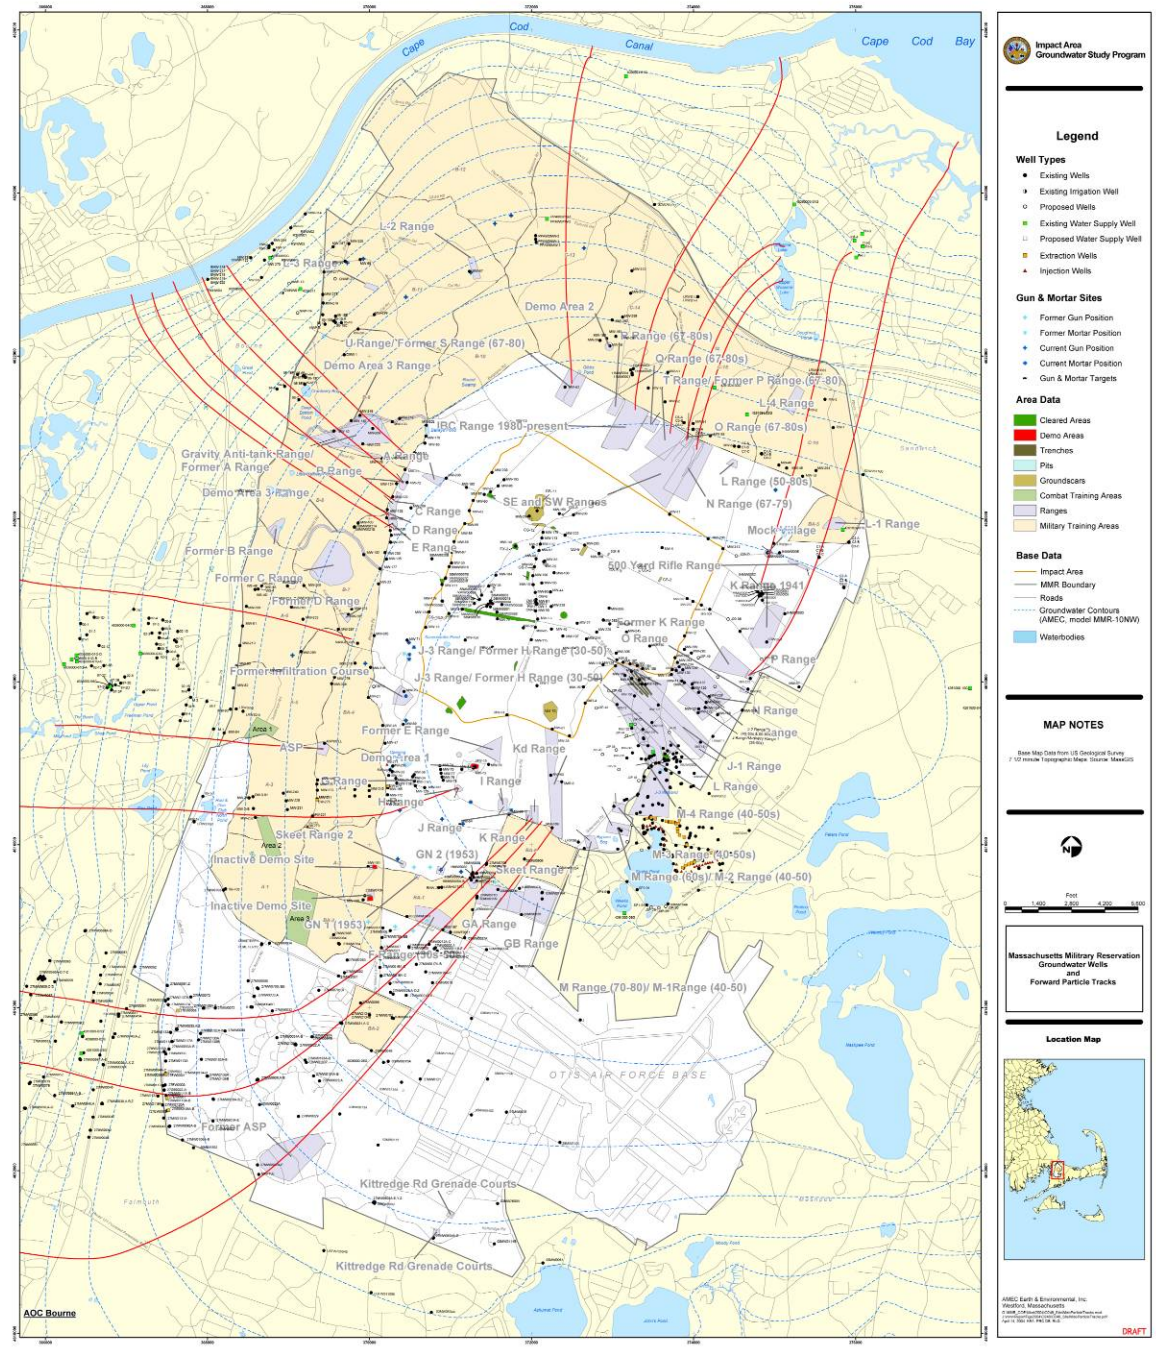

Figure 20. Particle tracks originating at all SARs where tungsten projectiles were used.

4.7 Task 8 – Speciation studies

Recently published research is beginning to describe the thermodynamics and kinetics of tungsten phase transformations and mineral associations. This research is in its infancy and currently is more descriptive than quantitative. Tungstate-solution chemistry is complex because, as reported in

Cotton and Wilkinson (1967), "....the alkali metal salts are water soluble... [and]... polymerize ...giving rise to a very complicated series of isopolyanions, the nature of which depends on the circumstances. In the presence of other elements, heteropolyanions can be obtained." The primary objective of the speciation studies was to identify the form of tungsten present in water and provide guidance for future toxicology studies. A secondary objective was to determine what happens to tungsten metal upon release into the environment and to identify the forms of tungsten present on the metal and soil surface after the occurrence of weathering, with the aim of establishing extent and mechanisms of tungsten adsorption to mineral phases present in the soil (Clausen et al. 2007a).

4.7.1 Tungsten speciation in water

Tungsten species present in solution at Camp Edwards were studied using a newly-developed analytical technique that separates tungsten species with HPLC, followed by quantification with ICP-MS (Bednar et al. 2007). This method has a detection limit of 0.4 µg/L for tungstate. To determine other species, however, higher concentrations are preferred. The concentrations of poly- and heteropoly-tungstates as a group can only be semi-quantitatively determined with this method because they interact to some extent with the anion exchange column. In addition, resolving the speciation of tungsten requires comparison with analytical standards that are apparently not available for all present species. The only standards available for comparison were for sodium tungstate and polytungstate; the latter is listed as having the following composition: $Na_6[H_2W_{12}O_{40}]$ or $3Na_2WO_4 \cdot + 9WO_3 \cdot + H_2O$. Polytungstates can be very complex, and the species in the standard may not be the same as the species in the soil solution.

Figure 21 compares the tungsten response curves for samples collected from lysimeters MMR-21 and MMR-30 against a standard containing polytungstate and tungstate. Lysimeter MMR-21 is located on C Range in the berm face at a depth of 165 cm bgs and was sampled on October 4, 2006 and November 8, 2007.

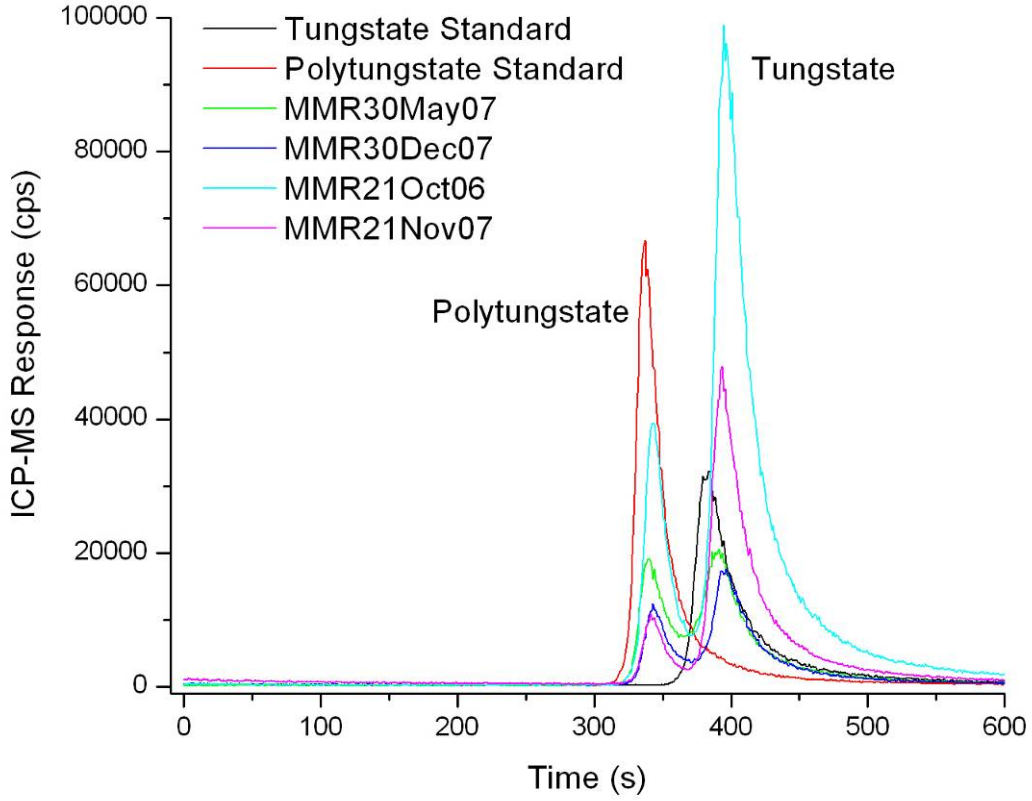

Figure 21. Speciation of tungsten in lysimeter samples from MMR-21 and MMR-30.

MMR-30, located on B Range, was installed on the berm face at a depth of 4.6 m bgs. MMR-30 was sampled on May 30 and December 19, 2007. The response curves for the lysimeter samples compare favorably to the curves for the polytungstate and tungstate standards, indicating both species are present. Reported total tungsten concentrations by ICP can be compared to the tungstate and polytungstate values obtained with HPLC separation (Table 14). The "total" tungsten values by ICP tended to be lower than the tungstate + polytungstate results. At the time of these analyses, the HPLC-ICP-MS method was semi-quantitative, and this caused the concentration differences. Values are sufficiently similar so that overall data interpretation is not affected.

As reported by Clausen et al. (2007b), a sample from monitoring well MW-72S was analyzed for tungsten using the speciation method of Bednar et al (2007). This sample, collected on May 10, 2006, had a reported tungsten concentration of approximately 550 µg/L.

Table 14. Total tungsten concentration compared to tungstate and polytungstate in lysimeters MMR-21 and MMR-30.

Lysimeter ID	Sample Date	Species Concentration (µg/L)			
		Total Tungsten (ICP)	Tungstate (SEC-ICP-MS)	Polytungstate (SEC-ICP-MS)	Ratio of Tungstate to Polytungstate
MMR-21	October 2006	18, 100	30,400	3,600	8:1
MMR-21	November 2007	10,000	14,100	980	14:1
MMR-30	May 2007	1,400	1,530	390	4:1
MMR-30	December 2007	1,400	1,170	230	6:1

The results for this particular sample indicated a good match with the sodium tungstate standard with polytungstate species not evident. These results suggested tungstate is the predominant species of tungsten migrating at Camp Edwards. The presence of polytungstate in the lysimeter samples shows that polymerization occurs in the vadose zone water. No significant difference exists between tungsate:polytungstate ratios for MMR-21 versus MMR-30; the latter is approximately 3-m deeper than the former. Thus, no appreciable attenuation of polytungstate relative to tungstate occurred over this depth interval. Attenuation of polytungstate relative to tungstate should result in increasing tungstate:polytungstate ratios. Evaluation of water from MW-72S (Figure 22), however, suggests polytungstates may not migrate as readily — a conclusion in agreement with other recently-published research (Bednar et al. 2008) that suggested attenuation occurred between 4.5 m and the water table (36 m).

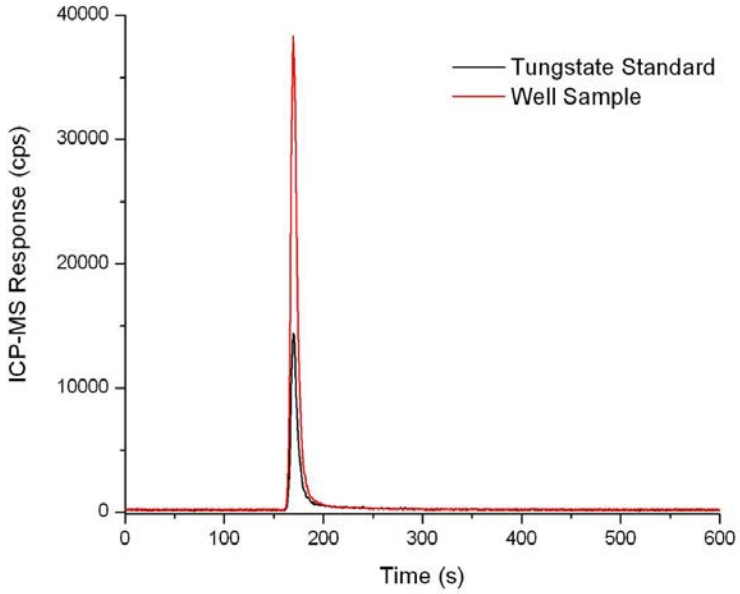

Figure 22. Speciation of tungsten in monitoring well sample MMR-72S.

4.7.2 Tungsten speciation in soil

ERDC/CRREL, in conjunction with Dartmouth College, plans to examine tungsten speciation in soils using synchrotron-based x-ray absorption spectroscopy (XAS). XAS, which is an element-specific probe of molecular structure, can detect trace quantities of specific tungsten species and provide a quantitative measure of their presence in soils and other complex media. XAS is unique in that it can be performed on whole soils without physical or chemical separations that alter speciation. The objective is to establish the extent and mechanisms of tungsten incorporation into stable mineral phases (e.g., tungstate minerals), and tungsten adsorption to mineral phases for which it has a high affinity, such as iron oxides and sulfide minerals. These data can then be used to improve the understanding of tungsten transport and bioavailability in soil systems. Information from this work was completed in February 2009 and will be documented in a separate report.

Preliminary tests suggest that tungsten metal oxidizes rapidly when exposed to the environment, and these oxides are short lived because they are transformed rapidly to tungstate species. In one test, tungsten metal powder was mixed with Camp Edwards' soil, and DI was added to make a slurry. After 24 hr, the water was removed, and the soil and tungsten metal were dried at room temperature for 72 hr and sealed in an airtight jar. XAS analysis of the soil sample indicated no presence of tungsten metal. In less than 1 week, all of the tungsten metal had oxidized.

5.0 Conclusions

Drive-point sampling at the aquifer interface, in addition to sampling and analysis of water from new monitoring wells, demonstrated that cessation of training with tungsten rounds and the subsequent soil removal project, limited the area of tungsten migration to groundwater within the vicinity of MW-72S on B range.

Results from shallow lysimeters (< ~ 160 cm) showed tungsten contamination remains in pore waters, although a weak decreasing trend in concentration is consistently observed. Three deep lysimeters (~ 1.5 to 7 m) installed at B range revealed that tungsten contamination existed in samples acquired over the entire depth interval. However, tungsten concentration also declined substantially with depth.

Laboratory and field experiments show tungsten dissolution may begin immediately upon exposure to oxidizing water, depending on the surface condition of the tungsten metal. The rate of dissolution under controlled conditions of temperature and water contact in the laboratory was relatively constant throughout the course of the experiment. The experiment demonstrated that mg/L concentrations of tungsten could be transferred to percolating waters in a matter of hours. Because of variations in temperature and rainfall, field dissolution was not as consistent but periodically supported the occurrence of rapid dissolution.

Batch experiments with six soils from Camp Edwards showed that K_ds ranged from approximately 20 to more than 450 mL/g. These findings are consistent with other recently published values, as was the conclusion that tests of 60 days or more were typically necessary to obtain a steady-state result. Sorption/desorption experiments with a variety of substrates and field-contaminated soil all demonstrated that desorption is less than sorption. Column studies with a contaminated soil (tungsten content ~ 52 mg/kg) showed some release of tungsten when leached with DI. The same soil, however, showed little or no loss of ability to remove sodium tungstate from a 10 mg/L influent solution. While these soils have substantial ability to remove tungsten, a small fraction remains mobile. Increasing the infiltration rate, as demonstrated in the column tests, will increase the amount of tungstate migrating through the soil and decrease the amount

sorbed. Under low infiltration, tungsten is greatly attenuated with little reaching groundwater.

Preliminary speciation studies showed that both tungstate and polytungstate(s) are present in the soil pore water at Camp Edwards, indicating the polymerization of tungstate. However, tungstate is the only species observed in groundwater. Tungsten migration appears to be somewhat controlled by a complex speciation pattern, which is probably dependent on pH, redox conditions, and time. For these reasons, unsaturated zone modeling using SESOIL and laboratory-generated partition coefficients (K_ds) did not mimic the mobility of tungsten as observed in lysimeters and monitoring wells.

The conceptual model for tungsten that is introduced into the environment as a result of training with tungsten/nylon projects at SARs is described as follows. Upon impact, the metallic tungsten/nylon round breaks up into micron-sized particles that are deposited upon the soil surface. Under windy conditions some tungsten particles may be deposited tens of feet from the berm face. Almost immediately, tungsten metal is oxidized, i.e. it rusts. Precipitation washes portions of tungsten oxides from the tungsten metal surface through a dissolution process and transports them in the form of tungstate. Some portion of the tungstate polymerizes in the vadose zone to form polytungstate species. In soils with low phosphate content, the tungstate/polytungstate is sorbed onto the soil surface. The greater length of time that tungstate is in contact with the soil surface results in a greater quantity of adsorbed tungstate and polytungstate; which is a function of the intensity of the precipitation event and resulting infiltration rate. Low-intensity precipitation events result in less tungsten dissolution and thus a lower rate of tungstate formation. Additionally, the infiltration rate is lower, causing longer contact time, which results in greater tungstate/polytungstate sorption as quantified by increasing K_d values. However, tungstate is also readily desorbed from the soil surface although the reaction is not completely reversible; some tungstate/polytungstate is retained on the soil surface. In locations with high soil phosphate content, the sorption sites are filled and limit the sorption of tungstate/polytungstate onto the soil surface. The presence of metal oxides such as aluminum increases the amount of tungstate and, presumably, polytungstate sorbed onto the soil. Tungstate that is not sorbed onto the soil migrates with water through the unsaturated zone. Polytungstate appears to be completely sorbed within the vadose zone. Tungstate moves

in the direction of water flow when reaching the groundwater table. The concentration of tungsten that reaches groundwater will be a function of the initial tungsten soil mass and the area over which it is deposited. Upon reaching groundwater, tungstate continues to be attenuated due to sorption processes, thus limiting its lateral migration. Tungstate reaches groundwater only under high-intensity precipitation events, resulting in a pulse-type release pattern. Consequently, tungstate concentrations from a fixed point in groundwater, such as a monitoring well, swing back and forth from relatively low levels (1 to 20 µg/L) to high levels (hundreds of µg/L), relatively quickly (days to weeks). This pulse pattern of release will result in small groundwater areas with elevated tungsten, sandwiched between zones of lower concentrations. Therefore, the area of groundwater contamination is likely to be discontinuous in nature, making detection difficult.

In summary, various field data and laboratory experiments demonstrate that tungsten from training rounds rapidly oxidizes and dissolves in percolating waters to form tungstate and polytungstate species. Sampling of numerous groundwater wells has shown that background concentrations are less than the 1 µg/L reporting limit. Any tungsten reported in groundwater and pore-water samples is therefore a result of oxidation, dissolution, and leaching from anthropgenically-derived sources.

Appendix A. Groundwater Monitoring Wells Sampled

Table A-1. Existing IAGWSP wells analyzed by ERDC-EL in Phase I tungsten SAR study.

SAR Wells	Background Wells
MW-72S (on B Range)	MW-135M1
MW-123M1 (downgradient of B and C Range)	MW-404S

Data for these wells has been previously provided in Clausen et al. (2007b), with additional Phase II ERDC-EL data provided in Table 2 of this report. These wells were sampled for the IAGWSP with sample splits provided to ERDC-EL and analyzed as part of the Tungsten SAR Study. STL-generated data is not provided in this report but is available from CENAE/IAGWSP.

Table A-2. Existing IAGWSP wells sampled to measure background.

Well ID	
MW-05M2	MW-151S
MW-07M2	MW-254M2
MW-62S	MW-280M2
MW-67S	MW-357S
MW-71M1	MW-404S
MW-79M2	

These wells were sampled by ECC for CENAE/IAGWSP and analyzed by STL with split samples provided to NAU. NAU analysis was conducted as an activity under the Tungsten SAR Study. The NAU data is provided in this report in Table 4. Additional analytical results are not provided in this report but are available from CENAE/IAGWSP.

Table A-3. Tungsten SAR study phase II wells.

Range	Well ID
B Range	MW-455S
	MW-490S
C Range	MW-491S
	MW-456S
SE Range	MW-465S
	MW-466S
Tango Range	MW-467S

These wells were installed for ERDC-EL by CENAE for the Tungsten SAR Study. Wells were sampled by ECC for CENAE with split samples provided to ERDC-EL. The ERDC-EL analyses were conducted as a part of the Tungsten SAR Study. The ERDC-EL data are provided in Table 6 of this report.

Appendix B. Results from Drive-Point Sampling

(Notes available at end of Table)

Appendix E. Substrate Effect on Sorption/Desorption Test Results

Methodology

In the sorption test, 4.5 g of material was placed into 4-oz amber glass jars for each media type, (see Section 4.4.1.2). Each media type consisted of three replicates. A 70-mL solution containing DI at a concentration of 10 mg/L of sodium tungstate was added to the 4-oz jars. The jars were placed on a shaker table at 100 rpm for 24 hr, removed from the shaker table, and allowed to settle for 2 hr. For some experiments, MMR22S1 soil was utilized, which contained 1,534 mg/kg tungsten. Experiments 25 through 36 used 4.5 g of MMR22S1 soil with a quantity of KPO_4 added. After 2 hr, a majority of liquid was removed, filtered, chilled, and sent to EL for analysis. Desorption experiments consisted of drying soil (typically for 1 week) to remove any remaining water from the sorption test. Seventy mL of DI was added to each 4-oz jar, which was then placed on a shaker table at 100 rpm for 24 hr. After shaking, the jars were allowed to settle for 2 hr, and an aliquot of solution was removed, filtered, chilled, and sent to EL for analysis.

Discussion

Note that data presented in this appendix should only be utilized for a qualitative assessment. Significant discrepancies exist between some replicate results (sorption experiment samples 13 through 15 and 31 through 33), and desorption experiment samples (10d through 12d, 15d and 15d dup, 16d through 18d, and 19d through 21d). In addition, all sorption samples were spiked at 10 mg/L, but many results are higher than those for the spiked concentration; this is problematic. Instrument data was reviewed by the analytical laboratory, but no errors were identified. The experimental protocol was also reviewed, and no errors were identified. Regardless, the experiments should be repeated in order to provide a quantitative assessment.

Cumm – cumulative; NA – not analyzed; Cl – chloride; W – tungsten.

Table F-3. Column 3. 1, Chloride tracer test and desorption test. Chloride spiked at 50 mg/L. Soil was 50:50 mixture of samples containing 52 mg/kg and 28 mg/kg of tungsten.

Appendix G. Unsaturated Zone Modeling Details

Introduction

SESOIL is a seasonal compartment model that simulates long-term pollutant fate and migration in the unsaturated zone. The purpose of this modeling is to determine if tungsten will eventually reach groundwater, and if so, at what concentration. SESOIL accounts for:

- Hydrologic processes in the unsaturated soil zone
- Pollutant concentrations and masses in water, soil, and air phases
- Pollutant migration to groundwater
- Pollutant volatilization at the ground surface.

SESOIL estimates the effects of these processes on a monthly basis during the simulation period. The modeled soil column may be composed of up to four layers; each layer has different soil properties that affect the pollutant fate. In addition, each soil layer may be subdivided into a maximum of 10 sub-layers in order to provide enhanced resolution of pollutant fate and migration in the soil column. The model can also account for the following pollutant fate processes: volatilization; adsorption; cation exchange; biodegradation; hydrolysis; and complexation.

SESOIL has been widely used as a screening tool in performing exposure assessments. A number of studies have been conducted on the SESOIL model, including sensitivity analysis, comparison with other models, and comparisons with field data. SESOIL has been used previously at MMR for fate-and-transport analysis of contaminants in the unsaturated zone and soil clean up-level determination (AFCEE 2003; AMEC 2006). This model has also been used to help in refining site-conceptual models and defining future risks to groundwater (AFCEE 2003).

Site-specific model set up and input parameters

SESOIL requires four sets of input data files as listed below:

- Climate data: consist of monthly rainfall and climatic statistics for a typical year, based on a specific meteorological station of interest
- Soil data: consist of soil parameters such as bulk density and effective porosity
- Chemical data: consist of chemical-specific parameters such as molecular weight, solubility, partitioning coefficients (K_{oc}), air and water diffusion coefficients
- Application input: describes compartment specifications, characteristics of pollutant loadings, thickness of soil layers, and additional soil properties beyond those specified in the soil input file (e.g., pH). Vertical variation in soil properties are established for lower layers, as a ratio of the information contained in the soil and chemical files that apply to the uppermost layer.

Specific data and sources for each input file are explained below; tables with input data have been presented by AMEC (2001).

Climate data

The weather station closest to Camp Edwards in the SESOIL database is the Hyannis weather station, which is located east of MMR. The database contains mean monthly data on precipitation and temperature, frequency and length of storms, cloud-cover fraction, and relative humidity. Default data from the Hyannis weather station were used except for precipitation. The mean monthly precipitation data acquired between 1976 and 2000 from the MMR weather station were used in the model.

Soil data

Soil data required by SESOIL includes bulk density, intrinsic permeability, soil pore disconnectedness index, effective porosity, and organic carbon content. Soil values are based on data collected at Demolition Area 1 at Camp Edwards as part of a column study (bulk density and soil porosity) conducted by the University of Texas (Speitel et al. 2002). For example, the soil-pore disconnectedness index was used as a variable within given constraints in order to obtain the approximate amount of groundwater recharge of 27 in.

Bulk density, intrinsic permeability, and effective porosity are all interrelated parameters. The analysis of soil sample data collected during previous MMR investigations (AFCEE 1998) indicates particle density of the soil matrix is approximately 2.65 g/cm^3. Using a total porosity of 0.42 (AMEC 2005; Speitel et al. 2002), the bulk density (soil-matrix density multiplied by total porosity) is approximately 1.5 g/cm^3. The general range for soil bulk density of sand is 1.18 to 1.58 g/cm^3 (Bonazountas and Wagner 1984).

Porosity was measured as part of column studies conducted on Central Impact Area soils by the University of Texas (Speitel et al. 2002). This value, which averaged approximately 42% (0.42) for surficial and subsurface soils, was used for all SESOIL simulations.

Soil intrinsic permeability and the soil pore disconnectedness index are model input parameters, which are not measurable in the field, but both can be estimated. Soil intrinsic permeability can be approximated by multiplying hydraulic conductivity by 1 x 10^{-5} cm s (centimeter s) (Bonazountas and Wagner 1984). A value of 5.0 x 10^{-9} cm^2 was used in this model. The soil-pore disconnectedness index relates the soil permeability to soil moisture content, and values typically range from 3.7 for sand to 12.0 for fine clay (Bonazountas and Wagner 1984). A value of 3.9 was used in this model.

Total organic carbon soil data collected from the Demo 1 project area were used to derive a specific value for percent organic carbon in the vadose zone. A value of 1.05% was estimated for the upper layer (0- to 1-ft bgs) from an average of organic carbon samples collected from this depth. This value is consistent with other areas of MMR. An organic carbon value of 0.34% of the surface value was used for the layer between 1- and 10-ft deep. Organic carbon values of 0.1 and 0.013% of the surface value were used for the two lower layers (10 – 80 ft and 80 – 90 ft), respectively, based on data collected at the Demo 1 area.

Chemical property data

Chemical property data used were the same as those used in previous SESOIL modeling efforts and were generally based on data obtained from the USEPA (1996) and RAIS database (ORNL 2005).

Application input

SESOIL allows a multi-layer soil column set up to model the contaminant movement throughout the unsaturated zone. Level of discretization is based on the modeling objective and thickness of the unsaturated zone.

A 19.8 × 10.7-m grid was used in this analysis. A depth to groundwater of 27 meters was used for the simulation. All four available model layers were used to represent the vertical stratigraphy. The upper layer (Layer 1) was 30.5-cm deep (equivalent to 1 ft) and divided into four sub-layers. The remaining soil column extending to the groundwater table was split into three layers (Layers 2, 3 and 4) of 300 cm, 2100 cm and 305 cm (10, 69, and 10 ft) respectively. The three lower layers used the maximum available number of sub-layers (10) in the model to describe the movement of contaminants in the unsaturated zone. The tungsten source is applied in Layer 1 as a one-time release, because training has been discontinued with tungsten ammunition. Thus, the mass in the source will deplete as a result of chemical processes and vertical dispersion as the contaminant migrates through the vadose zone.

Modeling calibration and sensitivity analysis

In this model, potential contaminants can only migrate to groundwater through the unsaturated zone by dissolving in the recharging water. Thus, recharge rate is a critical factor in the SESOIL model. SESOIL simulates hydrologic parameters (including recharge rate) and transport parameters of a contaminant in the unsaturated zone. Thus, model calibration is necessary for determination of a reasonable site-specific recharge rate so that fate-and-transport of a contaminant can be properly simulated.

Extensive model calibrations were conducted previously through a series of simulations that used various measured versus modeled values of moisture content and recharge rate with depth (AMEC 2005). Because this study used the same soil and meteorological parameters, the model required no further calibration. Using previously described climatic data and soil parameters, the following hydraulic parameters are predicted:

- Precipitation 118.03 cm
- Evapotranspiration 46.53 cm
- Surface runoff 0.03 cm

- Recharge to groundwater 71.49 cm
- Average soil moisture content in source zone 11.37%
- Average soil moisture content below source zone 11.37%

Results are in general agreement with the MMR site conceptual model and field data in western Cape Cod and are consistent with the modeling results conducted by USEPA/INL for the Tango Range [recharge rate of 27 in. per year (68.58 cm/year) and a calibrated soil moisture content of 12.3%]. Thus, detailed model calibrations were not performed.

AT123D model

The AT123D groundwater transport model (SEVIEW version 6.3; Environmental Software Consultants 2006) was used to predict groundwater concentrations downgradient of the source term. AT123D is a three-dimensional groundwater model developed by G. T. Yeh (1981) at Oak Ridge National Laboratory. Significant modifications were made by researchers (Schneiker 2006). This model can simulate advection, dispersion, sorption, decay, and biodegradation with results used to estimate the distance a contaminant will migrate for specific time periods and locations. Biodegradation was not used in this analysis to allow consistency with other IAGWSP investigations.

Site specific model set up and input parameters

AT123D requires two sets of input files; Aquifer and Source Release/Chemical Input Parameters. AT123D aquifer parameters contain information describing soil characteristics and aquifer geometry whereas AT123D input parameters contain information describing the geometry of the source release and contaminant properties. Because SEVIEW software links SESOIL to AT123D, the mass flux of the contaminant is transferred to the input load file in AT123D, as are other parameters specified in SESOIL.

Aquifer parameters

Effective porosity and soil bulk-density parameters are identical to the values used in the SESOIL model and were discussed previously. The

Demo 1 value of 3.68 m/hr, equivalent to 8,832 cm/day, was used for hydraulic conductivity, and specific gradients were scaled from maps and based on the sub-regional numerical model developed for the Demo 1 site.

Longitudinal, transverse, and vertical dispersivities were specified as 10.00, 2.0, and 0.0116 m, respectively. These values were recommended by USEPA/INL in the Tango range investigation.

The aquifer width and depth were set at infinity per modeling document guidance to provide an easier analytical solution. Because the aquifer boundaries are relatively large in relation to size of the source area, an infinite aquifer along the x and y directions is appropriate (Schneiker 2006).

Input parameters

The input parameters contain information describing the geometry of the source release and contaminant properties. The source term was oriented with the width (y axis) centered on the sample location and the length (x axis) parallel to groundwater flow. This configuration frames the starting and ending points of the release with the center of the downgradient edge oriented at 0,0. Thus, the four corners of the release area are designated (-x, y/2), (0, y/2), (0, -y/2) and (-x, -y/2), with a centerline defined as (0,0). A mixing zone depth of 3 m was used to provide mixing of contaminants with underlying groundwater.

The remaining chemical inputs are carried over from SESOIL and include organic carbon content, chemical distribution coefficient, and water diffusion coefficient.

Modeling calibration and sensitivity analysis

Model calibrations were conducted comparing AT123D with numerical transport codes that have been used repetitively at MMR (USGS MODFLOW code; McDonald and Harbaugh 1988). Analyses indicate that AT123D provides acceptable results comparable to numerical transport codes (Cain 2006). AT123D is more conservative in calculating contaminant concentration at the boundary because, unlike numerical transport codes, AT123D does not take into consideration the additional dilution from soil moisture recharge downgradient of the source area.

14. ABSTRACT

Batch and column laboratory studies performed tungsten metal in contact with water readily releases dissolved species, and soil partition coefficients (K_d) do not stabilize in batch studies for 30 to 60 days. The K_d values are highly variable, range from 18 to 477 L/kg, and are dependent upon the length of contact time. The rate of dissolution from a tungsten particle appears to range from 0.022 to 0.067 mg/day. These findings indicate metallic tungsten and tungsten oxides are rapidly dissolved under high-intensity precipitation events and are transmitted through the vadose zone soils as tungstate and polytungstate species. If tungstate reaches groundwater, it will continue to be adsorbed by the aquifer matrix, resulting in limited migration from the source area. Polytungstate migration is seemingly attenuated by adsorption processes that prevent it from reaching groundwater.

Executive Summary

In February 2006, the Governor of Massachusetts suspended the firing of tungsten-nylon rounds at Camp Edwards, Massachusetts after tungsten (15 µg/L or 15 parts per billion) was detected in a groundwater monitoring well. Recognizing that the tungsten-nylon rounds used at the ranges were the likely source, the Massachusetts Army National Guard (MAARNG) entered into discussions with the Environmental Management Committee (EMC), Massachusetts Department of Environmental Protection (MassDEP), US Environmental Protection Agency (EPA), and other stakeholders such as the Scientific Advisory Council (SAC) and the Community Advisory Council (CAC) to the EMC. The discussions established that a berm maintenance project to identify, excavate and consolidate tungsten impacted soil was the prudent course of action. In compliance with applicable local, state, and federal regulations, the soil would be field tested, excavated, and stockpiled on the range floor of two operational ranges, and covered on all sides with an impermeable geotextile-like material to prevent further potential leaching of tungsten into groundwater.

URS worked with the MAARNG to identify areas of the 13 SARs (B, C, D, E, G, I, IBC, J, K, KD (only relocated H berm), SE, SW, and T) where tungsten-nylon bullets had been fired. URS conducted pre-characterization screening, process screening and post-excavation screening by using an X-Ray Florescence (XRF) analyzer. URS denoted areas with tungsten concentrations in excess of 150 ppm and was then able to guide soil excavation.

This effort was generally limited to areas known or observed to exhibit significant impacts such as bullet pockets, impact berm faces, toe slopes, crest and back-berm. Depending on the range configurations and usage histories, limited excavation was also conducted on the berm crest, back-berm areas and drop areas behind targets. No soil sampling or removal was conducted for range firing lines, range floors, or the range fans at large.

Based upon 513 XRF pre-characterization samples, it was determined that seven (7) ranges (B, C, G, I, J, K and T) exhibited concentrations of tungsten greater than 150 ppm in berm soils that was uniform enough to warrant excavation and consolidation. During the course of soil excavation, a total of 599 additional XRF process samples were collected, and a total of 414 additional XRF post-excavation samples were collected to confirm and document that the tungsten-impacted soil above the 150 ppm threshold had been removed.

All excavated soil (approximately 4,615 cubic yards in total) was taken to one of two consolidation areas. Soil removed from Ranges B, C, and T were placed into a consolidation area on the northern half of the range floor at Range C. Soil removed from Ranges G, I, J and K was consolidated with the already existing tungsten impacted soil (previously relocated from Range H) on the range floor at Range KD.

Of the six (6) remaining ranges (D, E, KD/(only relocated H berm), IBC, SE, and SW) that did not meet the soil excavation and consolidation criteria, only three (3) of the pre-characterization XRF samples indicated the presence of surficial tungsten above 150 ppm and zero (0) of the below ground XRF samples indicated the presence of tungsten above the 150 ppm limit. Therefore, these soils were not excavated and stockpiled.

Background

In 1997, the EPA issued Administrative Order (AO) #2, which among other conditions, suspended the firing of lead ammunition and ordered the removal of lead munitions in and around the SAR berms. A berm soil maintenance project was conducted at Camp Edwards in 1998 in compliance with requirements articulated in the EPA AOs. Under this program, metallic lead was removed and leachable lead was fixed in soil at 16 ranges (A, B, C, D, E, G, H, I, J, K, KD, N, O, P, SE, and SW). Soils containing Toxicity Characteristic Leaching Procedure (TCLP) leachable lead concentrations greater that 5.0 mg/L were removed and/or treated in situ during the program. This project also involved characterization of the nature and extent of lead in and around the SAR berms at the 16 ranges in question.

After the EPA ban went into effect in 1997, the MAARNG began using small arms ammunition containing a tungsten-nylon core instead of a lead core. Tungsten-nylon bullets were used from 1999 to February 2006, when the Governor of Massachusetts suspended this activity after the U.S. Army Environmental Command (AEC) identified tungsten in groundwater.

The tungsten-nylon ammunition (also known as "green" or frangible ammunition) used at the SARs consists of a projectile composed of a high-density tungsten-nylon core and steel penetrator surrounded by a copper-alloy jacket. Frangible, or "soft," rounds are designed to break apart when they hit walls or other hard surfaces to prevent ricochets during close-quarters combat. These 5.56 millimeter (mm) rounds have been in use at the SARs since 1999 and since that time a total of approximately one million rounds have been fired as shown in Table 1 and highlighted in Figure 1.

Each tungsten-nylon bullet weighs 2.07 grams and is 97 percent tungsten (W) and 3 percent nylon or approximately 2.01 grams of W and 0.06 grams of nylon by weight per bullet. The slugs are fabricated of a compressed powdered tungsten/nylon mixture with individual tungsten grains ranging from 5-20 microns in size. Unlike lead bullets that will generally remain intact or splinter into pieces upon impact, a tungsten projectile will partially or wholly disintegrate after impacting the target, depositing a fine tungsten powder on the ground surface. Other materials present in the tungsten-nylon round include a copper alloy jacket on the exterior of the bullet, as well as a cup primer and a brass case. Based on the number of tungsten-nylon rounds fired at Camp Edwards over the 6-year period, it is estimated that approximately 4,860 pounds of tungsten has been deposited at the SARs where these bullets were utilized based on the following calculation:

(2.07 g W/bullet) x (1,027,400 bullets fired) = 2,126,718 g W (approximately 4,680 lbs)

From July through December 2005, at the request of the MAARNG and the EMC, the AEC sampled soil, pore water, and groundwater monitoring wells at I, C, and B Ranges. The goal of the sampling was to determine the fate and transport of tungsten in soil, pore water, and groundwater due to use of tungsten-nylon ammunition. The AEC also sampled for 11 additional metals, including lead, in the same media at each range to determine whether the presence of tungsten affected the mobility of these metals in soil and groundwater. The results of the soil and pore water sampling and the first of three rounds of groundwater sampling were received by the regulatory agencies in February 2006. The results of the testing conducted by the AEC in summer/fall 2005 identified tungsten at I, B, and C Ranges at concentrations ranging from of 17 to 1,534 mg/kg in soil, 0.07 to 400.2 mg/L in pore water, and 15 µg/L in shallow groundwater at B Range in MW-72. Tungsten was not detected in groundwater from any other wells sampled during the first round of sampling, although the wells sampled may not have been well suited for this purpose given their location and screen depth.

In February 2006, the MAARNG, under the direction of the Governor of Massachusetts, suspended the firing of tungsten-nylon rounds at 13 Camp Edwards' SARs. Recognizing that the tungsten-nylon rounds used at the ranges were the likely source of the tungsten contamination, the MAARNG initiated discussions with the Governor of Massachusetts, the EMC, MassDEP, EPA Region I, and other stakeholders to establish a prudent short-term management approach. The discussions established that a berm maintenance project would be initiated to identify, excavate, and consolidate tungsten-impacted soil.

Soil Excavation Criteria, Equipment and Methodology

Soil excavation criteria were based on an approach reviewed and approved by the MAARNG, the EMC, and subsequently discussed and coordinated with MassDEP and the EPA. Because there is no state or federal regulatory standard for tungsten in soil or groundwater, the MAARNG used the background level established in the AEC study of 1.5 µg/g parts per million (ppm). Soils that exhibited concentrations of tungsten at 100 times that of the background concentration (Massachusetts Contingency Plan definition of a "Hot Spot"), or 150 ppm and greater were targeted for removal and consolidation.

URS provided a field crew to pre-characterize the tungsten impacted soil, identify the horizontal and vertical extent of the impacted soil, guide the excavation and subsequently document this fieldwork. Under the direction of the US Army Corps of Engineers, their subcontractor ECC physically excavated and consolidated the impacted soil.

In order to identify soils exceeding tungsten concentrations of 150 ppm, URS utilized Innov-X XRF analyzers equipped with a 35 kV 20uA current x-ray lamps. During the first 5 days of soil characterization, an Innov-X apha series XRF analyzer was utilized. After experiencing data recording difficulties, an Innov-X XT series XRF analyzer was obtained and used for the remainder of the soil management effort.

These XRF devices provided a minimum detection limit (MDL) for tungsten of approximately 35 ppm with a range of error of +/- 15%. This MDL and data resolution was appropriate for identifying tungsten soil concentrations >50 ppm and was therefore adequate for accurately identifying tungsten impacted soil approaching or exceeding 150 ppm (the selected soil consolidation threshold). Because lead is a regulated heavy metal, it was also recorded. The Innov-X XRF was able to provide a MDL for lead approaching 10 ppm with a range of error +/- 5%. National Institute of Standards and Technology (NIST) XRF soil calibration standards were utilized to verify XRF accuracy daily as shown in Table 2.

NIST XRF Calibration Standards

Metal	Blank	Low	Medium	High
Lead (Pb)	0 ppm	18.9 +/- 0.5 ppm	1,162 +/- 31 ppm	5,532 +/- 80 ppm
Tungsten (W)	0 ppm	150 ppm	400 ppm	N/A

Standard deviation for tungsten averaged +/- 6.6% with range of –12% to 8%. NIST XRF soil calibration standards were not initially available during the pre-characterization of Range B, however a technician from Innov-X came to Camp Edwards to provide soil standards, calibrate the XRF and verify the XRF response factor. The XRF technician established that a 2.27 response factor should be applied to pre-characterization data from Range B and this data set has been adjusted accordingly.

On ranges with a static target line and established impact berms, pre-characterization was initiated by establishing a baseline along the target line at each range. A point of origin was established at the middle firing lane on each range and measuring tapes were extended from this

point of origin (location "0") both right and left along the target line immediately in-front of, and parallel to, the collection trench at the toe slope of each impact berm. Transects across the impact berms were conducted at regular offsets along, and perpendicular to, this baseline, as shown in Figure 2. An initial baseline transect was performed and then followed by transects both right and left of "0" origin at evenly spaced intervals away from the point of origin. Once transects were identified that exhibited tungsten concentrations consistently below the 150 ppm criteria in both surface and sub-surface soil, the distance between transects was halved and additional sampling transects were initiated, proceeding from the outer transect lines back towards the point of origin. This approach was utilized to rapidly define the extent of tungsten impacted soil by establishing the concentrations at the terminus of the most heavily used firing lanes and working away from the "0" transect at large evenly spaced offsets to establish the lateral extent of tungsten impacted soil followed by "splitting the difference" between outer transects in order to accurately define the required lateral limits of berm excavation. An actual transect layout across a berm is shown in Photo 1.

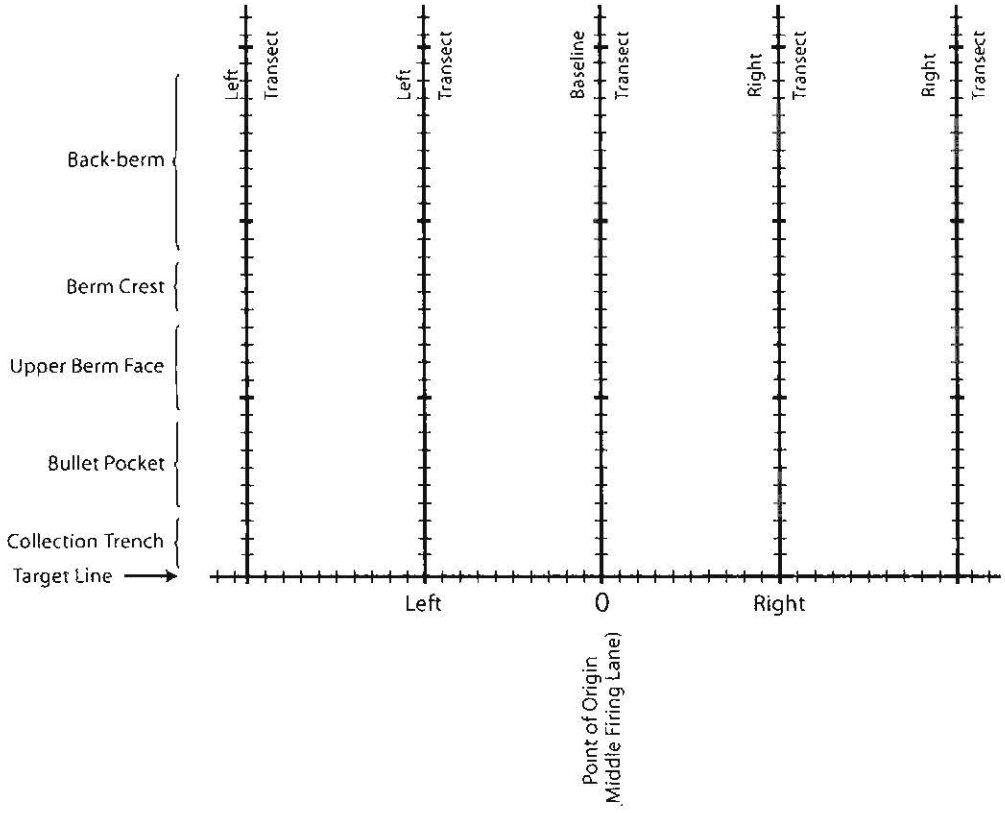

Figure 2 – TYPICAL TRANSECT LAYOUT

Photo 1
ACTUAL TRANSECT LAYOUT ACROSS BERM

In general, samples were collected along each transect at 5 berm locations at offsets shown in Figure 3 correlating with:

- toe slope/collection trench
- lower berm face/bullet pocket area
- upper berm face
- berm crest
- back-berm area

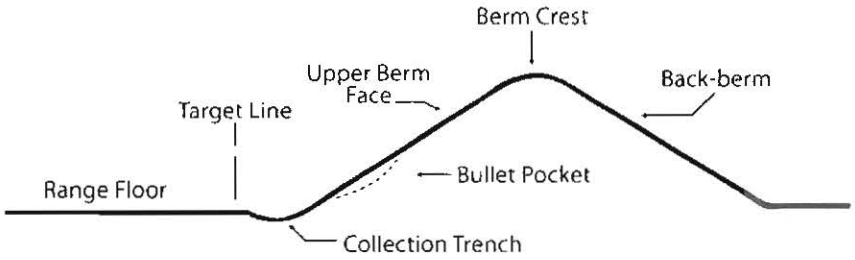

Figure 3 – TYPICAL BERM CROSS SECTION

At sampling locations, the XRF was used to screen soil at the following depth interval: surficial; 0-0.5'; 0.5'-1' and then at 1-foot or greater intervals, until tungsten concentrations were observed to be below 150 ppm. Based on this, a sample nomenclature was established indicating range ID, transect location (i.e. 0 or right/left of "0" by X number of feet), a measurement of sample location along each transect, and finally sample depth. An example of soil sample identification, based on this nomenclature, is as follows: B R100 15 1-2' which indicates a sample from Range B, 100 feet right of the point of origin along the baseline, 15 feet along the transect extending towards the berm perpendicular to the baseline and at a depth of 1-2 feet below ground surface. Ranges using this sampling nomenclature included B, C, D, G, I, J and K.

On Ranges E, IBC, KD/(only relocated H berm), SE, SW and T, the soil characterization effort and sample nomenclature were adapted to suit varying range configurations as static target lines and terminal impact berms were not uniformly present. Some of these ranges are "qualifying" or "battle course" ranges and the XRF characterization scheme was adjusted to better suit actual field conditions. Furthermore, MAARNG was in the process of upgrading and/or replacing the targeting systems at Ranges E, T, SE and SW. This resulted in the accumulation of piles of soil excavated from around targeting areas in order to install the new target systems and related components. On these ranges, XRF characterization efforts focused on soil piles of excavated materials that had been accumulated, as shown in Photo 2 for Echo Range. This was also the case at Range KD where the former berm materials from Range H had been previously deposited on the southwestern portion of the range.

Photo 2
ECHO RANGE UNDER CONSTRUCTION-TOPSOIL STOCKPILED ON RIGHT

Surficial soil samples were analyzed by field XRF in-situ by first clearing away any vegetative growth and "shooting" the topsoil in place. Subsequent soil samples were collected at depth utilizing a stainless steel hand auger. Soil samples collected via hand auger were placed between 2 layers of plastic and the XRF was subsequently used to analyze the composite soil sample sandwiched between the plastic sheets, as shown in Photo 3.

Photo 3
BERM SOIL SAMPLING AND XRF CHARACTERIZATION ALONG LOWER BERM FACE/BULLET POCKET

At each sampling location, fluorescent orange pin flags were then inserted into the ground and marked to indicate the excavation depth below ground surface necessary to remove soil exhibiting tungsten concentrations in excess of 150 ppm. Green pin flags were utilized to indicate areas where no excavation was required.

During excavation and consolidation efforts, URS worked with ECC to guide excavation efforts by collecting both process and post-excavation confirmatory XRF analysis. In areas where ECC had completed excavation to the depths indicated by the pre-characterization flagging, URS collected post-excavation XRF screening on 15-foot centers. In those areas where XRF data indicated that the remaining soil was below the selected consolidation criteria (<150 ppm), a green flag was placed. Conversely, in areas where tungsten concentrations were observed to be present at concentrations >150 ppm in soil to depths exceeding 3 inches, the fluorescent orange flags were replaced indicating that additional excavation of 0.5-1 foot of material was required. In some instances, the remaining post-excavation surficial soil and near surface soil (<3") indicated the presence of tungsten marginally above or approaching the 150ppm consolidation threshold. It appears that re-deposition of dust or soil knocked down from up-slope or shallower areas of the excavation had redistributed a thin veneer of tungsten impacted soil at the base of the excavation. URS worked with MAARNG to evaluate whether this material represented slough

and redistributed dust/fines or if the XRF results indicated that additional excavation was warranted. In general, if post-excavation base samples exhibited tungsten concentrations in soil less than the 150 ppm criteria at depths below 3", then no additional excavation was conducted.

Results and Observations

In general, no distinct tungsten-nylon bullet fragments were observed because of the propensity of the tungsten-nylon bullets to pulverize to a fine dust or powder upon striking a surface. The observation of fragmented copper, used as a metal jacket on the tungsten-nylon core, served as an indicator of the areas most likely impacted by tungsten-nylon bullets. Because the bullets generate fine particles of tungsten upon impact, tungsten at concentrations exceeding 150 ppm was detected in surficial soil samples at berm crests and in some cases, on the back-berm. This was generally the case at static target ranges backed with impact berms and with a history of high tungsten-nylon bullet use such as Ranges B and C.

Range pre-characterization screening commenced on May 17, 2006, process screening (which occurred during soil excavation) commenced on May 24, 2006, and post-excavation screening commenced on May 25, 2006. URS field efforts concluded on June 6, 2006. Based upon information provided by the ECC, a total of approximately 4,615 cubic yards of tungsten-impacted soil were excavated and consolidated (this total includes 1000 cubic yards of berm soil from H Range that was moved from H Range to KD Range back in 2003).

A total of 513 pre-characterization XRF samples were collected during this soil excavation and consolidation program. Table 3 - Tungsten Screening Summary, summarizes the number of pre-characterization, process screening and post-excavation screening XRF samples collected in the field; the percentage of samples that exceeded 150 ppm for tungsten; and the approximate depths of soil excavation by range. The complete pre-characterization results by range are summarized on tables in the Appendix.

Based on these pre-characterization results, it was determined that seven (7) ranges (B, C, G, I, J, K and T) exhibited concentrations of tungsten >150 ppm in the soil and the distribution of this impacted soil was uniform enough to warrant excavation and consolidation. On these ranges, 25% to 62% of the pre-characterization samples indicated the presence of tungsten exceeding 150 ppm. Soil from T range was also stockpiled with soil consolidated on C Range, although only 1 XRF screening sample from T Range was greater than 150 ppm.

N/A= Not Appliciable
Y=Yes, N=No

1. Values shown for relocated berm from H Range.
2. Primarily due to surficial redeposition/sloughing of soil during excavation. Limited to 0" to 3" below ground surface.

On the remaining six (6) ranges (D, E, KD(only relocated H berm), IBC, SE, and SW) that were not subject to soil removal and consolidation, only 1 percent of the pre-characterization XRF samples indicated the presence of tungsten above 150 ppm. On four (4) of these ranges (E, KD(only relocated H berm), SE and SW) none of the pre-characterization XRF samples were above the 150 ppm screening threshold. On the remaining two (2) ranges (D, and IBC), only one (1) surficial soil sample in each range exceeded the 150 ppm criteria (307 ppm at Range D and 370 ppm at Range IBC). Subsequent XRF soil screening samples collected at these two (2) ranges from the 0-0.5' depth interval resulted in readings which varied from non-detect to 50 ppm, indicating that the extent of tungsten impact did not meet this project's soil excavation and consolidation criteria. Pre-characterization of Range KD only included soils relocated to KD from Range H.

During the course of soil excavation at Ranges B, C, G, I, J and K, URS collected both process and post-excavation XRF samples in order to guide excavation activity and document that the extent of soil excavation was sufficient to remove tungsten impacted soil above the 150 ppm threshold. A total of 599 additional XRF process samples were collected during this phase of the soil consolidation program and a total of 414 additional XRF post-excavation samples were collected to document that the extent of the soil excavation was sufficient. The complete results of process and post-excavation sampling by range are summarized on tables located in the Appendix. The approximate location of soil removal by range is shown on Figures 4 through 7.

All excavated soil was taken to one of two consolidation areas. Soil removed from Ranges B, C, and T was placed into a consolidation area on the northern half of the range floor at Range C. Soil removed from Ranges G, I, J and K was consolidated on the range floor at Range KD. In the consolidation areas, an impermeable geotextile base sheet was placed on the range floor and overlain by wood chips prior to placing impacted soils on top of the wood chips. Impermeable geotextile sheeting was rolled out over the smoothly graded soil piles and overlapped with adjacent rolls. The sheeting was also overlapped with the base sheet so as to prevent stormwater runoff from washing into consolidated soils. The impermeable sheeting was suitably weighted with old tires linked together with rope and telephone poles laid along side the berm to prevent movement of the sheeting by wind. The ultimate disposition of this soil will be further evaluated by MAARNG as additional studies regarding tungsten fate and transport become available and as range-specific BMPs are implemented.

The US Army Corps of Engineers and ECC collected post-excavation composite soil samples from each range where soil excavation/consolidation occurred. These samples were submitted to an analytical laboratory for total tungsten analysis and the results from the samples were below 150 ppm for tungsten.

Abstract: Synchrotron-based X-ray absorption spectroscopy (XAS) of select surface soil samples obtained from Camp Edwards, Massachusetts, small arms ranges indicate that little tungsten metal remains in the soil and that is not stable in the natural environment. X-ray absorption near edge structure (XANES) studies indicate rapid oxidation of tungsten metal to form tungsten oxides W(VI), polytungstates, tungstates, and polyoxometallates (POM) in any number of forms. Owing to structural similarities, it is difficult to identify specific species or discriminate between mineral species, although polytungstates and POMs predominate as compared to tungstates in soil. Additionally, this is the first study to identify the presence of tungsten POMs in soil.

XANES spectra indicated that, as depth increased, the fraction of soil sorbed tungstate increased and both polytungstate and POM decreased, suggesting POM and polytungstates are more stable in surface soils and likely to persist, whereas tungstate is unstable. Tetrahedral tungstate is unstable in neutral and acidic pH solutions such as are present in Camp Edwards surface soils, resulting in its conversion to a variety of polytungstates. Adsorption of tungstate, although weak, appears to occur on iron oxide surfaces such as ferrihydrite. XAS studies also revealed prevalence of adsorbed polytungstates rather than discrete mineral phases.

Soil pore waters in equilibrium with contaminated soils during laboratory experiments yielded tungsten concentrations in excess of 5000 mg L^{-1}, considerably in excess of predicted solubility limits of common tungsten minerals. These findings are consistent with field observations whereby tension lysimeters installed in the shallow vadose zone to monitor the soil pore water at the Bravo Range at Camp Edwards had tungsten concentrations as high as 400 mg L^{-1}. The high solubility and limited adsorption of tungsten in these soils is attributed to the formation of POMs such as $W_{12}SiO_{40}^{4-}$, an α-Keggin cluster, in soil solutions in addition to other polytungstates. Polytungstates are quite soluble and can yield water concentrations of several hundred mg L^{-1}. Although, not detected in groundwater, possibly because of analytical limitations, the presence of polytungstates in the vadose zone pore water at Camp Edwards suggests their presence cannot be completely ruled out. In contrast, the presence of tungstates in groundwater has been confirmed at Camp Edwards.

The weak retention of tungsten, in general to soils and observation of tungsten in soil pore water and groundwater at Camp Edwards attests to tungsten's potential mobility and transport in groundwater. The slow rates of conversion between POMs, polytungstates, and tungstates are likely to affect their solubility and transport considerably. Additionally, the presence of iron oxides such as ferrihydrite and organic matter may limit tungsten mobility. In general, tungsten mobility from highest to lowest proceeds from Tungstate→ Polytungstate → POM → Tungsten Oxide → Metallic Tungsten.

Nomenclature

α–Keggin cluster Keggin structure is the best known structural form for heteropoly acids. It is the structural form of α–Keggin anions, which have a general formula of $[XM_{12}O_{40}]^{n-}$, where X is the heteroatom (most commonly P^{5+}, Si^{4+}, or B^{3+}), M is the addenda atom (most common are molybdenum and tungsten), and O represents oxygen. The structure self-assembles in acidic aqueous solutions and is the most stable structure of polyoxometallate catalysts

Preface

This report was prepared by Jay L. Clausen, Biogeochemical Sciences Branch (BSB), U.S. Army Engineer Research and Development Center (ERDC), Cold Regions Research and Engineering Laboratory (CRREL), Hanover, New Hampshire, Anthony Bednar ERDC-Environmental Laboratory (EL), Benjamin C. Bostick Columbia University, Jing Sun, and Joshua D. Landis, Dartmouth College, Dept. of Earth Sciences.

The U. S. Army Environmental Command (AEC) provided funding for this work. Dr. B. Packer (AEC) and Dr. S. Sobecki, CRREL, provided technical reviews.

The project team for this work includes the following:

- Technical Representative and Program Manager—Kimberly Watts (USAEC)
- Technical Project Manager—Dr. Bonnie Packer (USAEC)
- Principal Investigator—Jay Clausen (ERDC-CRREL)

Jay Clausen was responsible for communication with Kimberly Watts and Bonnie Packer of USAEC. The authors acknowledge the contributions of S. Taylor at CRREL

This report was prepared under the general supervision of Terrence Sobecki, Branch Chief, BSB, CRREL; Dr. Justin B. Berman, Research and Engineering Division Chief; Dr. Lance D. Hansen, Deputy Director, CRREL; and Dr. Robert E. Davis Director, CRREL. The Commander and Executive Director of the ERDC is Colonel Kevin Wilson. The Director is Dr. Jeffrey Holland.

1 Introduction

The U.S. Army Corps of Engineers, Engineer Research and Development Center, Cold Regions Research Engineering Laboratory (ERDC-CRREL), and Environmental Laboratory (ERDC-EL), were tasked by the U.S. Army Environmental Command (USAEC) to assess the fate-and-transport properties of tungsten leaching from tungsten-nylon bullets. The U.S. Army developed the tungsten-nylon bullet as a replacement for the lead bullet (Clausen et al. 2007). Metallic tungsten was believed to be essentially insoluble with little or no environmental mobility and thus environmentally benign. However, previous studies at Camp Edwards at the Massachusetts Military Reservation (MMR) demonstrate that powdered metallic tungsten used in these projectiles is mobile under some conditions (Clausen et al. 2007; Clausen and Korte 2009).

Prior to the previous decade, tungsten's environmental fate had not been studied in detail. Reasons included a lack of suitable analytical techniques as well as a general belief that tungsten was relatively insoluble and inert (Hartung 1991; Lassner et al. 1996; Langard 2001). This belief persisted even though the metallurgical literature had already suggested tungsten might be relatively soluble under appropriate conditions of pH and redox potential (Osseo-Asare 1982).

It is now known that, once deposited in metallic form, tungsten may be oxidized to soluble ions subject to leaching with percolating water. Therefore, the fate of tungsten ultimately depends on an accurate understanding of tungsten geochemistry. Unfortunately, the chemistry of tungsten in natural systems is not well understood; questions persist regarding what forms of tungsten are found in soils and to what extent solid-solution partitioning regulates tungsten concentrations.

The stable and soluble forms of tungsten under oxidizing conditions are tungstate (WO_4^{2-}) or oxide complexes in the +6 oxidation state. Study of tungsten's environmental behavior is complicated by its propensity to polymerize—a process favored at lower pH and higher tungsten concentrations—conditions potentially present in some firing range soils (Dermatas et al. 2004; Koutsospyros et al. 2006). Polymerization is the bonding of

two or more monomers, in this case tungstate, to form a polymer, i.e., polytungstate.

In principle, the thermodynamics of tungsten speciation are simple. Tungsten metal is unstable in the environment, and tungsten has for all practical purposes only one stable oxidation state, hexavalent tungstate (Baes and Mesmer 1986; Koutsospyros et al. 2006). Tungsten is nearly always found in one of a few mineral tungstates. In contrast to mineral forms, the solution chemistry of tungsten oxide complexes (Tungsten [VI]) is exceedingly complicated. Tungsten is similar to molybdate-forming variety of stable polyatomic anions, including $H_2W_{12}O_{40}^{-6}$, $HW_6O_{20}^{-3}$, and $W_6O_{20}(OH)^{-5}$ (Baes and Mesmer 1986). These species have well-known thermodynamic properties, with WO_4^{2-} stable in dilute and basic solutions, while the $W_{12}O_{40}^{-6}$ and related ions are stable in more concentrated solutions and acidic solutions. Within a narrow range of neutral pH, $W_6O_{20}(OH)^{-5}$ is also stable. Complications in tungsten speciation arise because interconversion among these forms is frequently slow, and numerous metastable ions, such as $W_4O_{12}(OH)_4^{-4}$, can persist in some solutions (Koutsospyros et al. 2006). However, the Koutsospyros et al. (2006) paper did not specify the rate of interconversion or degree of persistence.

Tungsten can also form a variety of polyoxometallates (POMs) in solution (Himeno et al. 2005; Chen et al. 2004). Polyoxometallates are cluster compounds containing two or more metal atoms that are similar in structure to polytungstates but are a different class of compound. Owing to structural similarities, it is difficult to distinguish between polytungstates and POMs. Tungsten POMs are constructed of WO_6 and a central MO_4 tetrahedron. One type of POM, known as an α-Keggin cluster ($MW_{12}O_{40}^{x-}$), has been intensively studied (Chen et al. 2004). Because of their exceptional size, molecular mass, structure, and chemical reactivity, a variety of other POMs are also known. Although some evidence suggests that such clusters are important in environmental systems (Furrer et al. 2002; Casey 2006), few studies have examined their formation in soils (Bednar et al. 2008). Furthermore, no thermodynamic data are available to predict the stability of tungsten POMs in soil systems, nor have they been conclusively identified in soils. Given the large molecular size of POMs, the expectation is that their mobility is low and thus would be retained in surface soil. Further, there is some evidence POMs are adsorbed onto soil to a greater extent than WO_4^{2-} and therefore are less mobile from a geochemical perspective.

Thermodynamic modeling of soil solutions with near-neutral pH based on known equilibria with common tungsten minerals (equilibrium with tungsten oxides including WO_3H_2O or $CaWO_4$) predicts tungstate concentrations of approximately 1 mg L^{-1}. In many cases, adsorption can keep tungsten concentrations much lower. Unfortunately, insufficient data are available to determine the reason for the high apparent solubility of tungsten in some soil environments and few studies have examined tungsten speciation in soils (Bednar et al. 2007, 2008). Certain questions have not been answered satisfactorily, such as: which tungsten mineral phase is present in soil and to what extent is adsorption important in regulating soil solution concentrations?

The operating conceptual model is that tungsten metal is deposited on the small arms firing range from the firing of a tungsten projectile. Upon impact with the soil surface, the tungsten-nylon pressed-powder core shatters, depositing micron-size tungsten metal particles. Tungsten metal rapidly oxidizes to form a tungsten oxide species W(VI) or WO_4^{2-}. The tungsten oxide is solublized and forms tungstates, polytungstates, and POMs species. Tungstate, under appropriate geochemical conditions, can also polymerize to form polytungstates. Depolymerization of polytungstate back to a tungstate is also a possibility, depending on the soil geochemistry.

During the oxidation process, a hydrogen ion (H^+) is released. If the tungsten mass is high enough and buffering capacity of the soil is low, acidification of the soil can occur, which could affect the speciation of tungsten, and the strength of tungsten adsorption. However, at Camp Edwards the surface soil is sufficiently acidic to favor polymerization of tungstate even without additional H^+ produced through oxidation. At some sites where the soil is borderline alkaline, polymerization would not occur on its own, but addition of H^+ from oxidation of metallic tungsten may be sufficient to start the polymerization processes. At sites where soil is sufficiently alkaline and the mass of tungsten introduced into the environment is low, polymerization of tungstate would not occur. If the rate of polymerization is slower than the precipitation infiltration rate, then tungstates will migrate deeper into the soil. If appropriate conditions are present at depth, tungstate will continue to polymerize to polytungstate as it moves downward. If the rate of polymerization is faster than the infiltration rate, polytungstate levels will build up in the shallow soil. Eventually, these polytungstates will be carried deeper into the soil profile. In contrast,

POM is strongly adsorbed to soil surfaces and, thus, is preferentially retained at the soil surface, unlike tungstate and polytungstate. So, in this report, we refer separately to tungstate, polytungstate, and POMs because of their different geochemical behavior and fate-and-transport properties. At Camp Edwards, then, the expectation is that the ratio of polytungstate to tungstate would increase with increasing depth and POM would remain tied up in the surface soil. A simplified conceptual model of tungsten mobility by soil depth is presented in Figure 1.

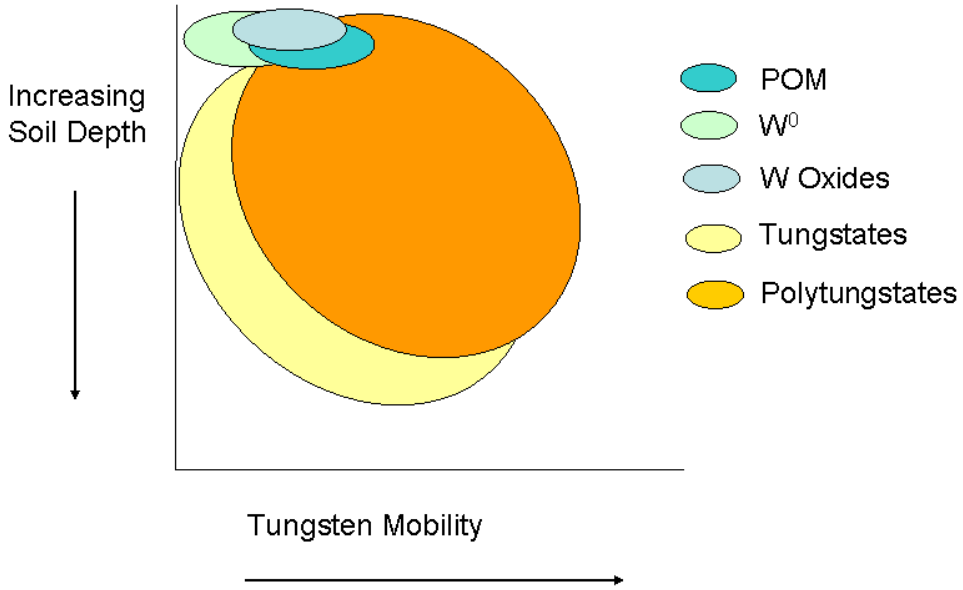

Figure 1. Conceptual relationship between tungsten mobility and soil depth.

Camp Edwards was chosen as a tungsten study site because tungsten-nylon projectiles had been fired there since October 1999 and detailed records were available for the number of bullets fired per range (Clausen et al. 2007). Tungsten measurements of soil and soil pore water at Camp Edwards found elevated levels present. Concentrations of tungsten in surface soils ranged as high as 2080 mg kg^{-1}. Samples from lysimeters installed into range berms showed tungsten in the soil pore water ranging to 400 mg L^{-1}. Samples from monitoring well MW-72S, located approximately 10 m down-gradient of the berm on Bravo Range, contained tungsten at levels between 0.005 and 0.560 mg L^{-1}. These findings raised concern that tungsten is migrating away from the small arms ranges and could affect down-gradient water supplies (Clausen et al. 2007).

This report is an extension of previous fieldwork documented in the Tungsten Phase I and Phase II Reports (Clausen et al. 2007, 2010) and fo-

cuses on tungsten speciation and solubility in a series of soils obtained from firing ranges where tungsten rounds were used. Aggregated, homogenized soil samples were collected from a variety of firing range sites at Camp Edwards (Clausen et al. 2007), and from two other sites: one in the northwestern U.S. and the other in the southeastern U.S (Clausen and Korte 2009). Mineral and adsorbed forms of tungsten were quantified using synchrotron-based X-ray absorption spectroscopy (XAS). Desorption isotherms for tungsten in these soils were used to characterize adsorbed phases. Results revealed complete and rapid oxidation of tungsten metal, and the prevalence of adsorbed polytungstates in soil solution rather than discrete mineral phases. Information provided in this report will assist the following organizations in future decision-making regarding tungsten's environmental behavior: U.S. Army, U.S. Army Environmental Command (USAEC), Impact Area Groundwater Study Program, and Massachusetts Army National Guard. It is expected that the U.S. Environmental Protection Agency, Massachusetts Department of Environmental Protection, and Environmental Management Commission for MMR should also find the information useful.

2 Objectives

The overall objective of this project was to develop an improved understanding of tungsten speciation in natural environments. This information is needed to accurately predict the fate of tungsten in firing range soils and in other contaminated environments. Thus, it is necessary to have a more complete understanding of tungsten geochemistry. Unfortunately, little is known about tungsten in environmental systems, and much of the data available concerning tungsten are conflicting. Field-based observations in some cases indicate that tungsten is highly soluble (Strigul et al. 2005; Bednar et al. 2008; Clausen and Korte 2009; Clausen et al. 2010), and tungstate adsorption to iron mineral phases in soil is strong, with rapid and complete adsorption under typical soil pH (Gustafsson 2003; Dermatas et al. 2004; Xu et al. 2006). To accurately assess the potential migration, and bioavailability, of tungsten (not the focus of this study), it is critical to understand tungsten's speciation or chemical form (focus of this study), and processes actively influencing its partitioning between soluble and insoluble mineral forms, and thus the extent to which these species are prone to leaching from surficial environments.

This research effort on tungsten-nylon fate and transport was divided into two phases. In the first phase, soil and soil pore water were sampled at three military installations; at one of the three installations, Camp Edwards, groundwater was also sampled (Clausen et al. 2007). Given that tungsten was detected in groundwater at Camp Edwards during four quarterly sampling efforts, a second phase of work (Clausen et al. 2010), focused on Camp Edwards, was funded to further understand the fate and transport of tungsten. In particular, the speciation work, which is the focus of this report, was funded in that second phase.

To meet the overall objectives for understanding tungsten migration and environmental behavior, the present study examined the speciation and solubility of tungsten in munitions-impacted soils primarily from three small arms firing ranges at Camp Edwards. A few samples from two other military installations were evaluated as points of comparison. X-ray absorption spectroscopy was used to determine the oxidation state of tungsten residues and to evaluate mineral and adsorbed forms of tungsten in these soils. This information is essential for evaluating the fate of

tungsten in these environments such that effective management decisions can be made regarding these training ranges. Investigations to identify tungsten-bearing phases included synchrotron-based microbeam spectroscopy, μ-X-ray fluorescence (μXRF) and μ-X-ray absorption (μXAS). Tungsten XAS has been applied to the study of tungsten catalysts and oxides (Michailovski et al. 2007; Montanari et al. 2008; Kelly et al. 2009), but has only recently been reported for natural materials (Bednar et al. 2008). Speciation data were then used to evaluate tungsten solubility from these soils using a series of desorption and sorption experiments. These data were used to propose a mechanistic link between tungsten speciation and solubility. Although these soils contain high levels of other metals (e.g., antimony, copper, lead, and zinc), the results gleaned from these studies should be generally applicable to an improved understanding of tungsten environmental geochemistry.

The tungsten work effort for Phase II was divided into a series of tasks. Task 1 consisted of development of a Work Plan for the field and laboratory studies. Tasks 2 through 5 included both field sampling of water and laboratory experiments. Tasks 6 and 7 involved groundwater modeling to predict migration rates through the unsaturated and saturated soil. Results from these tasks were reported elsewhere (Clausen et al. 2010). This report presents the findings of Task 8, a speciation study to ascertain the form or forms of tungsten present in the environment. Documentation of the results is Task 9. Detailed descriptions of each task are as follows, but note once again that only Task 8 is reported in this document.

- Task 1—Develop work plan.
- Task 2—Collect groundwater drive-point samples from several locations down gradient of the small arms ranges (Bravo and Southeast/Southwest Ranges) and install monitoring wells at (Bravo, Charlie, and Southeast/Southwest Ranges) at Camp Edwards to assess the nature and extent of tungsten and lead.
- Task 3—Install lysimeter clusters at depths of 1.5, 4.6, and 7.6 m (5, 15, and 25 ft) below ground surface at one location at the Bravo Range to assess the unsaturated zone transport rate of tungsten.
- Task 4—Determine tungsten dissolution rates from tungsten-nylon material via drip tests and conduct batch and column studies.
- Task 5—Do adsorption/desorption laboratory batch and column studies to quantify the interaction of tungsten and lead with MAECTITE™

treated surface soils, untreated surface soils, and subsurface soils under a variety of conditions.

- Task 6—Model the unsaturated zone to extrapolate from data collected in Tasks 2, 3, and 4 to predict tungsten transport rate across the entire unsaturated zone, i.e., approximately 36 m (120 ft),
- Task 7—Model groundwater using data from Tasks 2 through 6 to determine the tungsten transport rate and predicted extent in the saturated zone for all 12 small arms ranges at Camp Edwards.
- Task 8—Examine and explain the species of tungsten present in the environment.
- Task 9—Write Interim and Final Reports, documenting project management, and reporting.

3 Methods

High performance liquid chromatography-inductively coupled plasma-mass spectrometry (HPLC-ICP-MS) and size-exclusion chromatography-inductively coupled plasma-mass spectrometry (SEC-ICP-MS) were used to assess the species of tungsten present in water. Because tungsten can exist in multiple oxidation states and its speciation is poorly known, laboratory XAS, X-ray absorption near edge structure (XANES), extended X-ray absorption fine structure analysis (EXAFS), and X-ray microprobe analysis, including μXRF and μXAS, were used to identify and quantify the physical and chemical forms of tungsten in Camp Edwards soil cores and soil pore-water samples.

3.1 Site Selection and Sample Collection

Groundwater from monitoring wells, vadose zone pore water from tension lysimeters, and soil samples for speciation studies were collected as described previously (Clausen et al. 2007, 2010). Aggregated, homogenized soil samples were also collected from a variety of firing range sites at Camp Edwards (part of MMR), a northwestern U.S. site, and a southeastern U. S. site as previously described (Clausen et al. 2007; Clausen and Korte 2009). Tungsten munitions have been used at each of these ranges for as long as 5 years, and all were sampled within about 1 year (during 2006 and 2007) after tungsten usage ceased. Briefly, surface soil samples (0–5 cm depth) were collected from a variety of sites within the ranges, including firing points, the range floor, and at or beneath the targets and collection troughs. Additional sites at each location were selected as controls to examine background tungsten concentrations. Distribution of contaminants on ranges is variable because of the heterogeneous nature of their application. Therefore, each surface soil sample consisted of 100-increments following the *MULTI-INCREMENT*® sampling technique outlined in Hewitt et al. (2007). Soil samples were prepared following procedures outlined in Clausen et al. (2007, 2010). Briefly, the samples were sieved (to <2 mm) and homogenized (using a ball mill or mill grinder) prior to study. At two selected locations within the target zone, soil profiles were collected to 100 cm total depth to examine the tungsten vertical distribution. Identical depth intervals from four adjacent cores were aggregated to obtain representative soil samples, and each of these aggregated soil samples was sieved and homogenized prior to analysis.

3.2 Soil Analysis

3.2.1 Bulk Analysis

Soil samples for this effort had been collected and analyzed as part of Phase I activities (Clausen et al. 2007) prior to the current study. At that time, the bulk composition of soil samples was determined in the field using a field portable X-ray fluorescence (XRF) spectrometer (Innov-X Alpha-4000s) and in the laboratory by inductively coupled plasma-optical emission spectroscopy (ICP-OES) and ICP-mass spectrometry (ICP-MS). These earlier results are reported in Clausen et al. (2007, 2010).

Soil composition was determined a second time by Dartmouth College for this speciation work as part of Phase II activities by digesting 0.5-g aliquots of soil samples. As tungsten is relatively insoluble in acidic solutions, this digestion differs from most standard digestion procedures and those used by Clausen et al. (2007) during Phase I activities.

First, 0.5 g of homogenized soil was heated in 5 mL concentrated HNO_3 and 2 mL 30% H_2O_2 at 100°C, and this solution was evaporated to dryness. Once dry, 2 mL of concentrated HNO_3 was added to the digested soil and the solution again evaporated to dryness. Tungsten was recovered from the digested soil by dissolving the digestate in 2 mL of 20% NH_4OH, followed by sonicating and vortexing to ensure mixing. Once complete, 20 mL of a 2% NH_4OH/1% EDTA (ethylenediamine tetraacetic acid) solution was added and the resulting solution was filtered and diluted significantly (51 times, with a 0.2% NH_4OH/0.1% EDTA solution) prior to analysis using a Thermo Intrepid II inductively coupled plasma-optical emission spectrometer (ICP-OES). This instrument was operated in radial view, with blanks and quality control standards run every 5 samples, using drift-corrected standard curves. Use of NH_4OH and EDTA in the final extraction steps was necessary to maintain tungsten in soluble forms prior to analysis. Tungsten is spectrally rich, with several lines suitable for analysis. The 207.9-nm wavelength used for ICP-OES analysis had a detection limit of 6 $\mu g\ L^{-1}$, corresponding with a detection limit of <0.1 $mg\ kg^{-1}$ in the solid phase (accounting for any dilutions and digestion volumes).

3.2.2 X-Ray Absorption Spectroscopy

X-ray absorption spectroscopy was performed primarily on beam line 11-2 at the Stanford Synchrotron Radiation Laboratory (SSRL) located on Stan-

ford University in Menlo Park, California. Tungsten EXAFS analysis and XANES were also performed on a variety of samples. A 30-element germanium detector was used on beam line 11-2 (a 13-element detector was used on beam line 10-2 for some experiments) to collect absorption data in fluorescence mode. Sample slits for measurement configuration were 1 by 10 mm. The monochromator crystal reflection used was silicon (220) with a phi angle of 90°. Tungsten EXAFS spectra were collected from –235 to 900 eV about the tungsten L_3 edge. X-ray absorption near edge structure spectra were obtained at a sampling interval of 0.3 eV at the edge. Scans were calibrated by inflection of a tungsten metal foil to 10207.0 eV (the maximum in the first derivative).

All data averaging, normalization, and linear combination fitting was done with SIXPack software (Webb 2005). Spectra were then normalized with linear pre-edge and quadratic post-absorption edge functions. Resultant normalized XANES data were compared to a library of tungsten standards. The edge positions of the XANES spectra are mostly similar (the tungstates are all tetrahedral tungsten (VI), and thus all have similar edge shapes and spectral features). Normalized tungsten L_3-edge EXAFS spectra were converted to chi functions with k^3 weighting and then compared to reference spectra in an analogous process. Tungsten EXAFS and XANES spectra obtained for contaminated soils were also compared to a spectral library of commonly encountered reference compounds, including sodium tungstate (Na_2WO_4), sodium polytungstate ($Na_6[H_2W_{12}O_{40}]$), wolframite ($FeWO_4$), scheelite ($CaWO_4$), sodium phosphotungstate ($Na_4[PW_{12}O_{40}.nH_2O]$), tungsten oxide ($WO_3$), and tungsten metal ($W^0$) from commercial sources, as well as intact, fresh tungsten-nylon bullet cores. Mineral standards were obtained from the Dartmouth College Dana Mineral Collection, and chemical reference materials were obtained from Fisher Scientific or Strem Chemical (for the tungsten metal foil). All spectra were processed using SIXPack software (Webb 2005). Spectral processing included background subtraction, spectral normalization, and fitting a spline function to isolate scattering features. The resulting XANES and EXAFS spectra were then fit with linear combinations of similarly processed spectra obtained from pure reference materials. For final fitting, EXAFS spectra were fit to determine the relative concentration of each reference compound. Fitting yielded the fraction of each tungsten model compound within each sample. These fractions can then be converted to final soil concentrations by multiplying by the analyzed total solid concen-

trations from total digestion followed by ICP-OES (or XRF) analysis results.

Accuracy of least-squares fitting depends on the chosen reference standards representing the variation in the spectra of soil samples and having sufficiently different spectra that they can be differentiated. In this case, for example, tungsten metal from commercial sources (pure) could not be differentiated from the tungsten metal used in the bullet cores themselves, and only one metal standard is thus used in fitting. Similarly, true tungstates (not polytungstate or octahedral pseudotungstates) are all quite similar and difficult to differentiate in fitting. For this study, mineral reference spectra are chosen on the basis of known and inferred speciation and thermodynamics data, and mineral associations implied that are based on elemental correlations determined in X-ray microprobe analyses. Errors in least-squares fitting are best estimated based on comparisons of fits of known mixtures, which account for fitting error (usually small) and systematic errors such as in background fitting because of self absorption (particularly for XANES spectra)—which can be important when model compounds are used to represent complex mixtures. In the case of known mixtures, accuracy of fit depends on the quality of reference spectra (they should be noise "free," well calibrated, free of self absorption, etc.), the extent to which spectra are differentiated, and spectral processing. In the case of tungsten XANES, the sharp edges of tungsten compounds are separated by 2–3 eV (Kelly et al. 2009), which is large enough to calculate fractions of each oxidation state very accurately (to quantify the fraction of metallic tungsten for example); however, fitting of EXAFS spectra were used in all final fits to quantify each mineral component. In known mixtures, fractions of tungsten species are typically fit to within 3–4% of known ratios based on fits of spectra of mixtures containing equimolar mixtures of tungstate and tungsten metal. In general, the precision of results for EXAFS fitting is about 5% (O'Day et al. 2004), based on spectral fitting of mixtures with known composition.

3.2.3 X-ray Microprobe Measurements

Microprobe X-ray fluorescence (μXRF) was used to determine the distribution and association of tungsten with various mineral phases in soils. X-ray microprobe images were collected at the SSRL on beam line 2-3 or the National Synchrotron Light Source (NSLS) located at the Brookhaven National Laboratory in New York on beam line x26A. Both beam lines use Kirkpatrick-Baez focusing optics to focus the incident beam (to a nominal

beam size of 1–2 μm at SSRL, about 5 μm at NSLS). These samples were prepared by mounting a thin film of unconsolidated sediment grains on Kapton tape. X-Ray fluorescence spectra were collected at 13,000 eV by continuously rastering the beam across the sample every 5 μm (10 μm at NSLS), and measuring the XRF spectrum for 250 μs at each point (2 s at NSLS). Regions of interest were defined for a number of elements, including tungsten, calcium, copper, iron, manganese, potassium, silica, sulfur, titanium, and zinc, and the integrated counts for each were used to estimate elemental abundance. While counts are proportional to concentration, it is difficult to determine accurate concentrations from this method without standardization and accounting for variable sample thicknesses. Therefore, all data are presented as fluorescence counts, I_F, normalized to incident intensity I_0 (I_F/I_0). Because grain mounts are of variable thickness, sample absorbance ($\log(I_0/I_1)$) was used to estimate sample thickness and density—a plot of this absorbance (or transmittance, I_1/I_0) shows the distribution of grains quite clearly. The effect of variable thickness on elemental abundance can influence element correlations. This effect is accounted for by normalizing counts using transmittance; however, this normalization did not affect overall elemental correlations and is not used in the presented data.

One of the special qualities of X-ray microprobe measurements is that they allow both composition at high spatial resolutions (the grains scale), and they also have tunable (variable energy) X-ray sources that allow spectroscopy to be performed on specific locations within an X-ray map to conclusively identify individual grains. In particular, using the same instrument and optical configuration, it is possible to collect microprobe X-ray absorption spectra (μ-XAS) at specific regions on an individual grain of interest. This can be done using the microprobe beam lines at either beam line 2-3 at the SSRL or beam line X26a at the NSLS. For these μ-XAS measurements, regions of high and average tungsten concentration were chosen for XAS study, and XANES spectra were obtained (by varying the incident energy from below the L_3 edge of tungsten using a method similar to the method described above for bulk soils) at these points. In some cases, iron *K*-edge spectra also were obtained at the same point to correlate iron minerals to the presence of specific tungsten phases. Iron XANES spectra were obtained by varying the incident energy to the sample from about 100 eV below the iron *K*-edge (7112 eV) to about 200 eV above the edge. This method was highly successful at identifying specific minerals responsible for tungstate retention, and for identifying discrete tungsten miner-

als, which also have distinct iron spectra (if they contain iron). Linear-combination fitting was also used for these spectra, although in most cases only a single mineral phase is needed in fitting, in agreement with the observation that most measurements made are at the grain scale and thus are composed of single minerals. Iron minerals used in fitting included ferrihydrite, hematite, goethite, biotite, hornblende, and pyrite, which were obtained from the Dartmouth College Dana Mineral Collection. Linear combination fitting of iron spectra, however, is slightly less accurate for iron minerals (within about 7% for mixtures of Fe[III] oxides, better for reduced minerals) because many of the spectra are similar over a large *K*-range. Nevertheless, iron *K*-edge XANES is highly effective at identifying and quantifying crystalline iron oxides, ferrihydrite, iron silicates, and other phases in soils.

3.3 Desorption Isotherms

To better understand the nature of tungsten retention in soils, tungsten was equilibrated with soil water solutions to obtain desorption isotherms (Koopmans et al. 2004). A desorption isotherm for a single, representative contaminated soil (from a bullet pocket at Camp Edwards, sample MB036S3) was created by varying the solid-solution ratio between 0.2 and 6.8 g mL^{-1}(Appendix A). Subsamples of MB036S3 were made by adding different amounts of distilled water to a given dry mass of soil (between 30 and 120 mL were added to 12 to 300 g soil). Replicate samples were chosen for selected ratios to estimate sample homogeneity and found to yield results within 1% of dissolved tungsten. Resulting mixtures were equilibrated on a shaker table for 51 hours at 22°C. This length of time was chosen to allow the system to equilibrate, and was sufficient for tungsten concentrations in solution to stabilize. The resulting suspensions were centrifuged (4000 rpm for 10 minutes), and the solutions were filtered (with 0.2-µm Nylon filters) to remove residual solids. Unfiltered samples were also evaluated to determine the extent to which suspended colloids were present in the solution. These had identical concentrations to the filtered samples, indicating a lack of colloids, and are not discussed further. Filtered solutions were then divided into aliquots for tungsten analysis, major- and trace-element analysis, and pH measurements. Samples reserved for tungsten analysis were prepared by diluting 9:10 with a 2%NH_4OH/1%EDTA solution to preserve aqueous tungsten and analyzed immediately by ICP-OES as described in Section 3.2.1. Samples for major- and trace-elemental analysis were diluted 9:10 using 5% HNO_3 and determined immediately by ICP-OES using conventional methods. The pH was

not controlled in these measurements, but was buffered by reaction with soil minerals and was measured in final solutions using a standard, calibrated pH electrode. The total tungsten soil concentration of each sample was estimated on the basis of both soil digestions and XRF data; the residual concentration of solid-phase tungsten was determined using the total tungsten concentration and measured solution concentrations following equilibration.

Desorption experiments are useful to characterize the mechanisms of tungsten retention in soils. If a solid mineral phase limits concentrations, then the concentration of tungsten in solution should be constant and not depend on the level of tungsten in the solid phase, at least until the solid is no longer present, at which point the solution concentration will be controlled by the quantity of mineral in the system. In contrast, adsorption equilibria result in nonlinear relationships between solid- and aqueous-tungsten concentrations.

Tungsten in these systems is clearly controlled by adsorption processes, so resulting isotherm data are fit with both Langmuir and Freundlich isotherms. These isotherms are both commonly used to describe adsorption processes. The Langmuir isotherm is characteristic of a fixed number of sites of constant reactivity and usually is quite effective in describing adsorption of simple anions. The Langmuir isotherm has an adsorption maximum corresponding to the surface area of the solid. If solution concentrations are very high, then the surface will be fully saturated and any tungsten in the system will not be retained by the solid phase. In contrast, the Freundlich isotherm indicates a range in sites of differing energies and has no adsorption maximum. It is used to describe cation adsorption if cations can precipitate, but also can describe anion adsorption in some cases.

A single mean desorption isotherm for tungsten also was created using 23 representative soil samples (19 from Camp Edwards and 2 each from the southeastern and northwestern sites) at a constant solid–solution ratio. These soil samples were prepared as described above using a soil-to-solution ratio of 0.3 g mL^{-1}. The desorption test provides information on how strongly or weakly tungsten is adsorbed onto the soil surface and, combined with a speciation analysis, will show which species is preferentially desorbed.

3.4 Adsorption Isotherms

To better ascertain the role of adsorption on tungsten retention, a series of adsorption isotherms were calculated for tungstate adsorbing on ferrihydrite. Ferrihydrite was selected for these tests as earlier X-ray microprobe studies indicated that this was the primary iron species adsorbing tungstate. Ferrihydrite was synthesized using the method of Schwertmann and Cornell (1991) by rapidly titrating a $FeCl_3$ solution to pH 7 with sodium hydroxide. For these studies, W(VI) solutions (0–100 mg L^{-1}) were reacted with ferrihydrite suspensions (1 g L^{-1}) for 48 hours at room temperature. Tungsten was added as a sodium tungstate salt. Experiments were performed in 0.002 Molar tris(hydroxymethyl)methylamine (TRIS) buffer (adjusted to pH 7 with 0.1 M NaOH and HNO_3). Parallel isotherms were obtained for tungstate adsorption in the presence of 1 mg L^{-1} silicate (added from a stock solution of sodium silicate). Following equilibration, the pH was confirmed to be unchanged and the resulting suspension was sampled, filtered to remove solids, and preserved with a 2%NH_4OH/1%EDTA solution. The tungsten concentration of this solution was then determined immediately by ICP-OES as described previously to avoid the potential tungsten precipitation in mineral forms.

3.5 Solid-Solution Speciation Modeling

The geochemical model MINTEQ was used to predict the stable thermodynamic phases in desorption isotherm experiments, and the equilibrium tungstate adsorption in adsorption experiments. Visual MINTEQ v. 2.61 (Gustafsson 2009) is an equilibrium speciation model used to calculate the equilibrium composition of dilute aqueous solutions from adsorption–desorption experiments. MINTEQ is designed to describe aqueous speciation and mineral equilibria in soil environments, and has been recently updated to incorporate the latest thermodynamic data for all elements in solution. This is important for desorption experiments as many aqueous components are released into solution and an accurate assessment of their chemical forms is needed to properly describe tungsten solubility and complexation. In addition, this speciation program incorporates the most recent thermodynamic data for tungsten solids and solution complexes, and is particularly well suited for the study of ferrihydrite adsorption. Equations and equilibrium constants for tungstate, calcium, carbonate, and silica sorption to ferrihydrite were used without alteration, but include the most recent thermodynamic data for tungsten complexation and adsorption (Gustafsson 2003). It should be noted that no speciation

program contains formation constants for most complex tungstate ions, and only simple polytungstates are included because they are stable from a thermodynamic standpoint. However, numerous ion pairs and other polytungstates, including polyoxometallates containing tungsten and other elements, may exist in the solution for either thermodynamic or kinetic reasons, and these complexes may not be described using MINTEQ or other thermodynamic approaches. Equilibrium adsorption was modeled using a 2-pK diffuse layer model with a single surface site, with a specific surface area of ferrihydrite of 100 $m^2 g^{-1}$. The surface area of ferrihydrite in this system was determined using a 3-point (Brunauer-Emmett-Teller) BET isotherm with nitrogen gas. The model was modified for different experiments, to match their respective solid (ferrihydrite) to solution ratios, arsenic loadings, and solution compositions. MINTEQ's ferrihydrite adsorption database was used, which includes reactions and constants from Dzombak and Morel (1990), as well as updates with more recent thermodynamic data.

Adherence of observed adsorption data to theoretical models would suggest adsorption is well described in these soils with established chemical reactions, while significant deviations would indicate additional reactions not currently in the database need to be considered. This is likely because the MINTEQ databases, although the best available for tungsten complexes, still only contain a few of the myriad species that may be present in multi-component environmental solutions. Alternatively, and somewhat less likely, deviations may also indicate that the equilibria are correct but have improper equilibrium constants, possibly because they were derived from overly simplified experimental conditions.

3.6 Outdoor Dissolution Tests

Two tungsten/nylon cores were set outdoors in 2-cm-diameter Buchner funnels atop liter bottles. The two cores, labeled W1 (dark) and W2 (silver), weighed 2.06 and 2.07 g, respectively. Rainwater or snowmelt that fell onto the tungsten cores was collected in the bottles. Approximately every 2 weeks, the bottles were changed, the water volume measured and aliquots of the samples analyzed. No water samples were collected over the winter (December 2006–April 2007) when the experiment was covered with snow. The W1 core was sacrificed for other tests on November 2007 and the W2 test was stopped in July 2008. The details of this test are discussed in Clausen et al. (2010) and all data are provided in that document.

4 Results/Discussion

4.1 Tungsten in Soils

4.1.1 Soil Concentrations

Soil concentrations of tungsten varied widely within the firing range, and were generally much higher than background levels, about 1.5 mg kg^{-1} (Clausen and Korte 2009; Clausen et al. 2010). In impact berms, bullet pockets, and other areas directly receiving munitions, soil tungsten concentrations were as high as 5500 mg kg^{-1}. Concentrations varied widely and were generally much lower in other portions of the firing surface (Table 1, Clausen et al. 2010). Tungsten concentrations also dropped rapidly with soil depth. Composite soil depth profiles showed consistent trends in tungsten concentrations, with high concentrations in the surface soils, and dropping rapidly to near-background levels (1 to 2 mg kg^{-1}) at depth.

Although tungsten is concentrated at the soil surface, it is important to note that measurable tungsten is present at soil depths in excess of 50 cm. Tungsten munitions have been used for relatively short times at these ranges, less than 5 years. Detection at depths in excess of 50 cm implies tungsten has been transported downward from the soil surface where either intact tungsten bullets or bullet fragments were deposited. This transport may result from soil mixing but also suggests some fraction of the soil tungsten is labile and rapidly mobilized.

In summary, the following observations can be made about small arms range soils where tungsten-nylon projectile have been used:

- Soil tungsten concentration varied by site, with the highest concentrations observed at Camp Edwards, Massachusetts.
- At Camp Edwards, soil tungsten concentrations were a function of the number of tungsten projectiles fired.
- Tungsten soil concentration declined with increasing soil depth.

Table 1. Summary of tungsten concentrations for soil samples used in this study. Errors reported reflect the standard deviations of triplicate measurements where applicable.

4.1.2 Tungsten Speciation in Soil

4.1.2.1 X-Ray Absorption near Edge Structure Spectroscopy

X-ray absorption spectroscopy provides information about the oxidation state and speciation of tungsten in intact soils. This technique, therefore, can be useful for identifying and quantifying the presence of the various tungsten species and mineral forms present. For example, tungsten XANES was used to identify the fraction of metallic and oxidized tungsten in each soil sample. The XANES spectra of all soil samples overlapped and did not vary with depth or sampling location. The spectra of each soil sample contained an inflection edge at 10,210.9 eV followed by a strong white line feature at 10,213.5 eV (Fig. 2). These features are characteristic of tungstate, the fully oxidized W(VI) form stable in most soil environments. There were no observable spectral features at lower energy that is characteristic of metallic tungsten (which has an edge at 10,207.1 eV and considerably lower white line intensity), indicating little if any metallic tungsten was present in the soil samples.

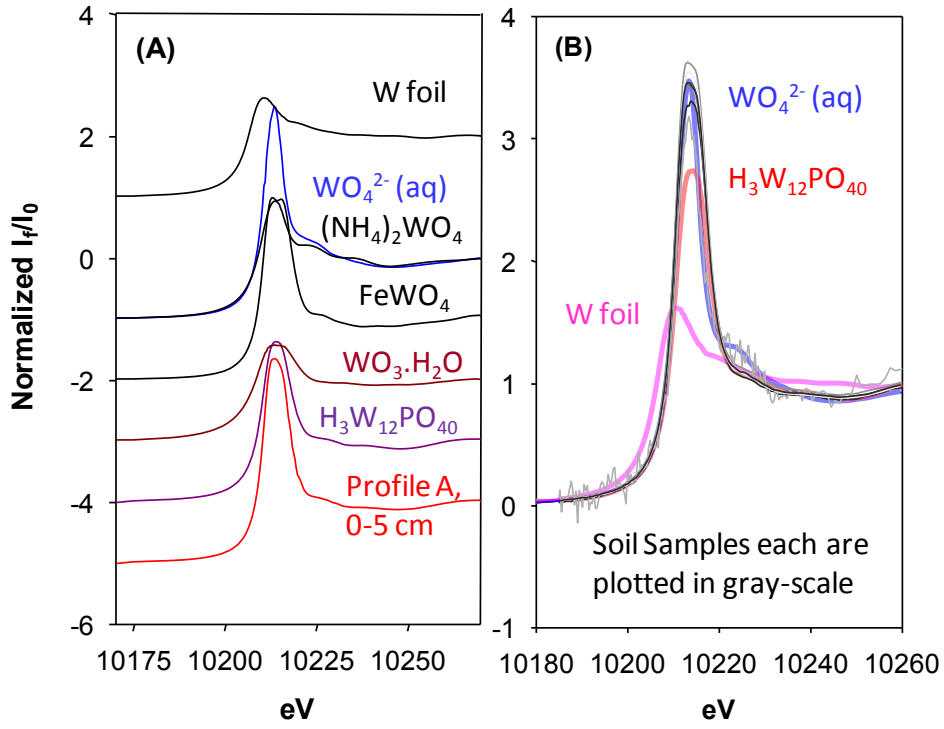

Figure 2. XANES spectra of selected reference materials (A) and (B) 10 representative soil samples from profiles A and B.

The position of oxidized W(VI) minerals is similar to all reference materials, and is easily distinguished from tungsten metal. The spectra of soils

are similar to that of tungstate (and polytungstate) and distinct from metallic tungsten. Least squares fitting of XANES spectra indicate >98% of the tungsten in each sample is W(VI). Further, these spectra indicate that tungsten metal in the munitions has been converted to tungstate, W(VI), or polytungstates of any number of forms, in the soil (Fig.3).

In summary, the XANES spectroscopy indicated the following:

- No tungsten metal is present in surface soils, indicating it is fully oxidized.
- Spectra indicate the presence of tungstate and polytungstate, suggesting the oxidized tungsten species are transitory and easily solublized.

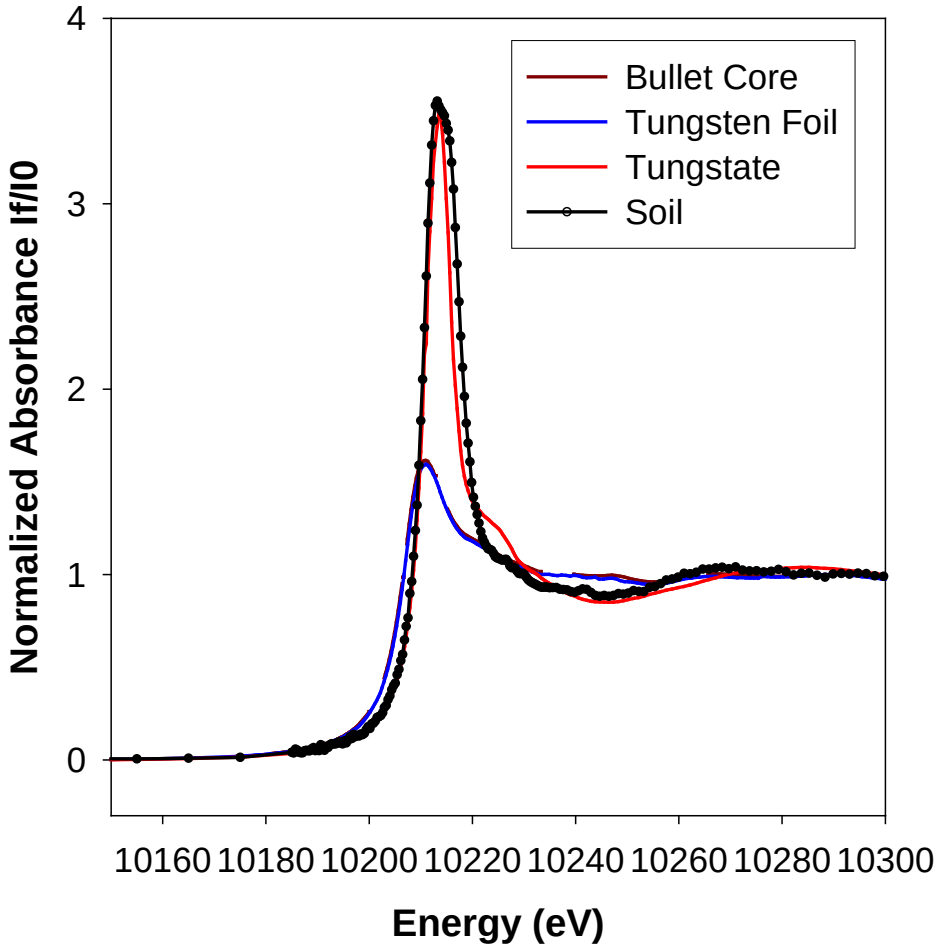

Figure 3. Tungsten L_3-edge XANES spectra of tungsten metal, tungsten in a bullet core compared to tungsten in soils, and tungstate (as sodium tungstate). Soils are nearly identical to tungstate. The spectrum of the bullet core is nearly the same as tungsten metal foil.

4.1.2.2 X-Ray Absorption near Edge Structure Interpretation

The fraction of tungsten metal and tungstate present in these samples was estimated using linear combination fitting of the XANES spectra. All spectra were adequately fit with only a single reference standard of sodium tungstate, with fits indicating 98% of tungsten in each sample was W(VI). This preponderance of oxidized tungsten has important implications for the fate of tungsten in the environment. Clearly, tungsten metal is not stable in soil environments. Tungsten was added to the soil as tungsten metal and had only a few years to oxidize. Given the limited time of environmental exposure, it is somewhat surprising the tungsten metal has rapidly and completely oxidized to tungstates and polytungstates. However, these results are consistent with the rapid release of dissolved tungsten from bullet cores as they react with water (Clausen et al. 2010). Furthermore, results indicate that the environmental fate of tungsten in these soils does not depend on the initial oxidation state of tungsten, as metallic tungsten (W^o) but rather depends on how oxidized tungstate species interact with soils.

The exact tungstate or polytungstate species sorbed to the soil is unknown, although precipitation of calcium and iron tungstates and polytungstates are possibilities (as will be discussed here), as are adsorption complexes on Fe(III) oxides (Gustafsson 2003). It is important to realize that the major form of tungsten in these samples is of critical importance for accurately assessing fate and transport. Occasionally, differences in the white line (the large peak in the XANES spectrum) intensity of tungstate and polytungstates can be used to differentiate between them (Pauporte et al. 2003). In our case, however, this distinction does not appear to be possible because the XANES spectra of different tungstates and polytungstates are sufficiently similar. The XANES spectra closely resemble polytungstate, and there is some evidence of splitting of the white line feature, which is also consistent with the spectra of polytungstates. The presence of polytungstates is more easily examined using EXAFS spectroscopy.

To summarize:

- Tungsten metal, W^o, from tungsten-nylon small arms ammunition is not stable in soil environments.
- Tungsten oxidation in the environment is not a limiting step in tungsten mobility.
- Mobilization of tungsten depends on how tungstate reacts with ions in the soil environment.

4.1.2.3 Extended X-ray Absorption Fine Structure Analysis Spectroscopy of Model Compounds

For extended EXAFS of tungsten to be used to characterize tungsten speciation in soils, it is necessary to collect spectra of prospective model compounds used as reference standards in fitting. Many of the spectra have not been published previously. These reference standards are used to establish that spectra are sufficiently different, and to confirm our methods are able to differentiate them.

Extended X-ray Absorption Fine Structure spectra depend on the structure of tungsten in a given mineral phase. For example, ammonium tungstate is a simple tungstate salt, with tungsten(VI) in tetrahedral coordination to four oxygen atoms. The EXAFS spectrum of tungstate is dominated by oscillations attributed to tungsten-oxygen (W-O) bonding (Fig. 4), and to few other features in the spectrum because the other atoms around tungsten are either light (low atomic number) or sufficiently far from the tungsten atom in the structure that they do not contribute to the spectrum.

Extended X-ray Absorption Fine Structure spectra can be used to determine the structure of atoms around a specific atom (in this case, tungsten). The ability to extract this structural information, and to do so without external standards, is quite powerful and is very useful to the study of structures for which we do not have model spectra. The structural data from known compounds can be compared with known structures for model compounds, but also yield new information used to characterize the mineral structure. Table 2 contains the structural data for the tungsten model compounds used in this study.

Tungsten model compounds can be separated into four principal groups: (1) tungsten metal; (2) true tungstates, WO_4^{2-}, which have tetrahedral tungstate; (3) complex metal tungstates containing disordered WO_6 polyhedra rather than tetrahedra; and (4) polytungstates and oxides, which also have disordered WO_6 polyhedra but also have tungsten-tungsten (W–W) shells. Each of these classes has distinct structural environments and is easily differentiated using EXAFS. Representative spectra from each of these classes of compounds are presented in Figure 4.

Tungsten metal has several W-W shells, which create a complex and well-defined interference pattern in the EXAFS spectrum that is easily differentiated from the other environments. This interference pattern results in

the presence of one or more nodes in the sine waves of the EXAFS spectrum (Fig. 4, left), where two waves deconstructively interfere, and spectral intensity (the *y*-axis) is diminished. Each wave creates one "peak" in the Fourier-transformed spectrum (Fig. 4, right). This Fourier transformed spectrum is called a radial structure function and can be imagined as a radial view of the density of atoms around the tungsten atom, with its size and shape depending on the element, its coordination number and its disorder; and its relative position determined by the distance of the atoms from the tungsten atom.

In contrast, tungstate spectra are much more complicated because the coordination environment of tungsten(VI) is highly variable. True tetrahedral tungstate (Class 2 in Table 2), although stable in alkaline solutions, converts to a variety of polytungstates in neutral and acidic pH solutions common to soils (Baes and Mesmer 1986; Koutsospyros et al. 2006). The spectrum of simple tungstate is dominated by a single, sharp W-O shell at 1.78 Å (Table 2). This shell is highly ordered, and is intense relative to other tungstates and polytungstates (Class 3 and 4 in Table 2), which have structures distinct from true tungstates.

The Class 3 and 4 tungstates and polytungstates are not true tungstates but instead are usually tungsten oxides, with complex W-O coordination because of multiple W-O shells. Many of these tungstates have tungsten in a disordered octahedral coordination to oxygen (coordination number 6). The highly disordered nature of the W-O shells makes the octahedral W-O shell have a much lower intensity than tetrahedral tungstates. The Class 4 polytungstates and tungsten oxides also usually contain a W-W shell because they are polymeric, and tungsten, if present in the local bonding environment, results in considerable scattering. The scattering results in a second peak in the Fourier-transformed spectra (Fig. 4, right side), making Class 4 polytungstates and tungsten oxides easy to differentiate from Class 3 tungstate minerals. In summary, each of the types of tungsten that could be encountered in the environment (Classes 1 to 4) have structural differences affecting their EXAFS spectra and provide a basis for identification and quantification in natural samples.

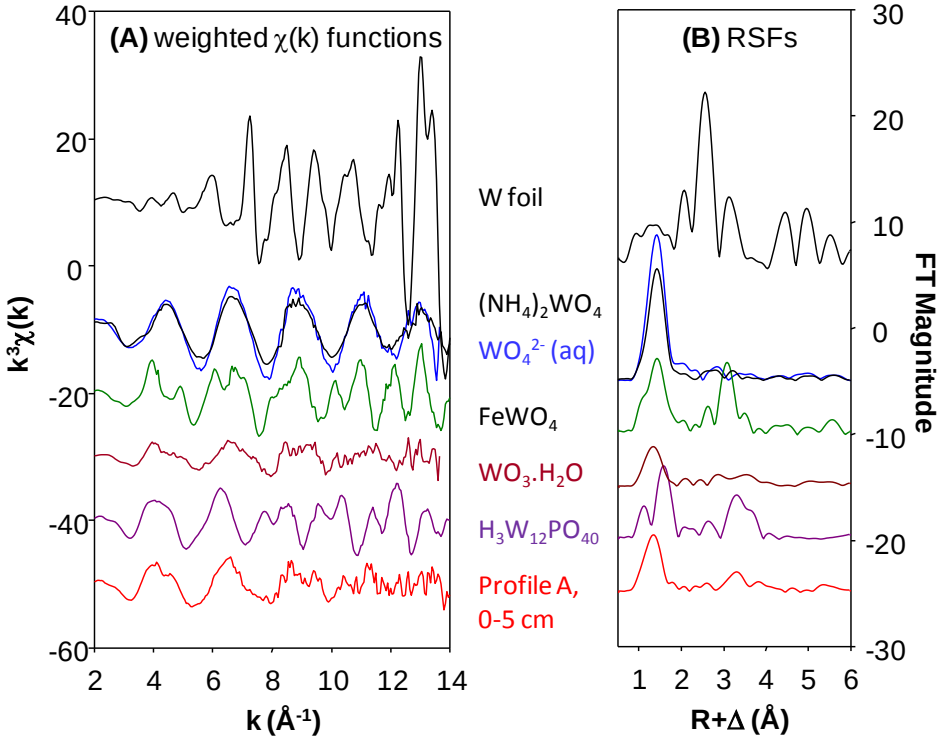

Figure 4. Chi functions (A) and radial structure functions (B) of select tungsten model compounds and a representative spectrum from soil profile A from the Camp Edwards site. Profile A consists of composite soil samples (MMRBLB073B, MMRBLB074B, and MMRLB075B) collected from the lower berm of Bravo Range at Camp Edwards near Targets 23, 26, 30, and 34.

In fact, tungstate minerals and polytungstates such as scheelite ($CaWO_4$) and wolframite ($FeWO_4$) are not true tungstates. Scheelite has disordered cubic coordination (Table 4), while wolframite is made up of WO_6 octahedra similar to those in polytungstates, and as a result, has similar spectra, with the exception that the second shells are of varying (smaller) intensities. Tungsten oxide, WO_3(s), is an insoluble oxide containing disordered WO_6 polyhedra linked in much the same fashion as polytungstates. The W-W distances in WO_3, however, are much longer than polytungstates (3.79 Å vs. 3.49–3.6 Å for $H_3W_{12}PO_{40}$), and the coordination numbers are higher, as would be expected of a condensed phase. Consequently, it should be possible to differentiate POMs and polytungstates from these W(VI) minerals based on their EXAFS spectra.

Table 2. EXAFS fitting parameters for select tungsten reference materials.

Sample	Shell	CN	R (Å)	σ^2 (Å^2)
Class 1: Tungsten Metal				
Tungsten metal (from bullet core)	W-W	8[a]	2.74	0.005
	W-W	6[a]	3.16	0.005
	W-W	12[a]	4.47	0.008

	W-W	2[a]	3.63	0.011

(a): Fixed during fitting based on crystallographic data. The coordination number (CN) is typically accurate to within ±1, inter-atomic distance (R) within ± 0.02 angstroms (Å); σ^2 represents the variance in R (in Å^2). For all of the reference materials, E^0 was ≈ 10,211 eV, except tungsten metal, which was 10,207 eV.

One interesting class of tungstates that may be adsorbed in soils systems are the POMs, and it is important to understand their structure and spectra so that we might identify them if present in soil environments. Numerous POMs of tungsten exist (Chen et al. 2004) but little is known about their existence in environmental systems, although some data suggest such complexes could form in soils (Bednar et al. 2007, 2008). Although a number of POMs can form readily with common ions in solution (e.g., silicate, phosphorous), no thermodynamic data exist in the literature on the stability of such complexes in aqueous solutions, or for their adsorption to soil minerals. In other words, information useful for predicting POM prevalence in environmental systems is lacking and POMs have not been observed directly in soils prior to this study. Tungsten POMs are similar in structure to polytungstates, which makes it difficult to differentiate between POMs and other polytungstates based on EXAFS alone.

While the identity and distances to the heteroatoms (the metals other than tungsten in the structure of POMs) are in principle useful to differentiate between different POMs (Manceau 1995, Manning et al. 1998, Morin et al. 2008) and tungstates, identification is complicated for POMs. POMs and other polytungstates also contain W-W shells that are intense and mask the effect of a single, smaller atom such as Si and these W-W shells, making it difficult to conclusively identify which POM, if any, is present in soils.

The structure and EXAFS spectrum of two common and potentially relevant POMs is known. In the spectra of silicotungstate and phosphotungstate, two substituted POMs, there are two W-O shells, at about 1.7 and 1.9 Å, respectively, that are similar to the bonding environment of both class 3 and 4 tungstates in Table 2. The similarity with “simple polytungstates” and tungsten oxides (Class 4 compounds), however, make it much more complicated to identify specific polytungstate phases, or to differentiate polytungstates from mineral phases. In fact, polytungstates and many tungstate minerals are each composed of disordered WO_6 octahedra with similar bond distances, and each has second shells between 3 and 4.5 Å in the radial structure function attributable to tungsten-tungsten (W-W) or other shells. These second shells are quite complex and are composites of a number of different structural components of similar distance, and in many cases, destructive interference between these many structural components lowers the overall intensity of the second shell. This structural he-

terogeneity between these materials is sufficient to complicate spectral fitting even for pure reference compounds with known structures.

To summarize:

- EXAFAS can differentiate among mineral tungstates, adsorbed tungstate, and polytungstates based on their structural differences.
- Even with the use of EXAFS, it is exceedingly difficult to identify specific polytungstate species or discriminate between mineral phases.
- Additionally, POMS are similar in structure to polytungstates thus differentiation with EXAFS is difficult.

4.1.2.4 EXAFS Interpretation of Tungsten Speciation in Contaminated Soils

The accurate quantification of tungsten species in contaminated soil depends on fitting the EXAFS spectra of soils with linear combinations of known reference spectra. The effective implementation of linear combination fitting depends on the unique spectral signature of each model compound identified in the soils. In principle, the reference spectra for each model compound have unique characteristics, allowing each to be fit independently; however, the similarities in spectra required the aggregation of model compounds into representative components that were sufficiently distinct spectrally. Moreover, some polytungstates, such as $W_6O_{20}(OH)^{5-}$, may be found in soils, particularly at near-neutral pH (Baes and Mesmer 1986; Koutsospyros et al. 2006), but no reference spectra are available for such materials. To address these limitations, least squares fitting of EXAFS spectra was performed using only four reference spectra: tungsten metal, tungstate solution (representative of Class 2 true tungstates, adsorbed tungstate, and WO_4^{2-}), wolframite (a Class 3 tungstate: a model tungsten(VI) mineral solid), and $H_3PW_{12}O_{40}$ (a Class 4 polytungstate: a model POM with known structure and spectrum). Attempts at fitting with WO_3, H_2O, and $CaWO_4$ did not yield stable fits owing to their similarity with $FeWO_4$. These four reference spectra should be regarded as model compounds representative of tungsten mineral classes rather than discrete species because of spectral similarities. For example, fitting with $H_3PW_{12}O_{40}$ does not imply that phosphotungstic acid is present in soils (although it may well be considering that the soil was treated with MAECTITE™—a phosphate based fixation agent), rather it is representative of polytungstates more generally. The implication is that it is not impossible to more conclusively identify POMs, or specific mineral phases, but such determinations depend on W-W distances and coordination

numbers obtained from conventional fitting of selected spectra. Other analytical methods, including X-ray fluorescence, also can be used to establish mineral phases based on composition.

In summary:

- EXAFS fitting of model compounds indicates it is possible to identify and quantify four distinct classes of tungsten in soils: tungsten metal (absent), true tungstates (Class 2), tungstate minerals (Class 3), and polytungstates or POMs (Class 4).
- It is not possible to differentiate among specific POMs or some mineral phases based on linear combination fitting alone owing to their structural (and spectral) similarity.

4.1.2.5 Tungsten Speciation with Depth Using EXAFS

Extended X-ray absorption fine structure analysis spectra of the contaminated soil profiles revealed consistent changes in tungsten speciation with depth (Fig. 5). All samples, Profiles A and B, regardless of depth or location contained insignificant (5±7% or less) tungsten metal in agreement with XANES data. Profile A consists of composite soil samples (MMRBLB073B, MMRBLB074B, and MMRLB075B) collected from the lower berm of Bravo Range at Camp Edwards near Targets 23, 26, 30, and 34. The profile B sample was obtained from a single core in the trough on Bravo Range near Target no. 31 (samples MMRB0510 through MMRB5060). Additionally, crystalline tungstate minerals like $FeWO_4$ never represented a majority of tungsten in the soils, although it is clearly more prevalent than tungsten metal. In fact, in most samples, adsorbed polytungstates or other POMs, $H_3PW_{12}O_{40}$, appeared to be the dominant fraction of soil tungsten throughout the soil profiles. The fraction of adsorbed tungstate (Class 2, true tetrahedral WO_4^{2-} adsorbed to soil minerals) was also significant, and generally increased with soil depth (as the total tungsten concentration decreased).

However, because the total concentration of tungsten decreased with depth, adsorbed WO_4^{2-} concentrations do not appear to increase with depth. The increased prevalence of tungstate at depth, which is more stable in basic solutions, may reflect the neutral and slightly alkaline pH of deeper soil horizons, while polytungstates are more stable in acidic to slightly acidic conditions of surface soil horizons (Baes and Mesmer 1986; Koutsospyros et al. 2006).

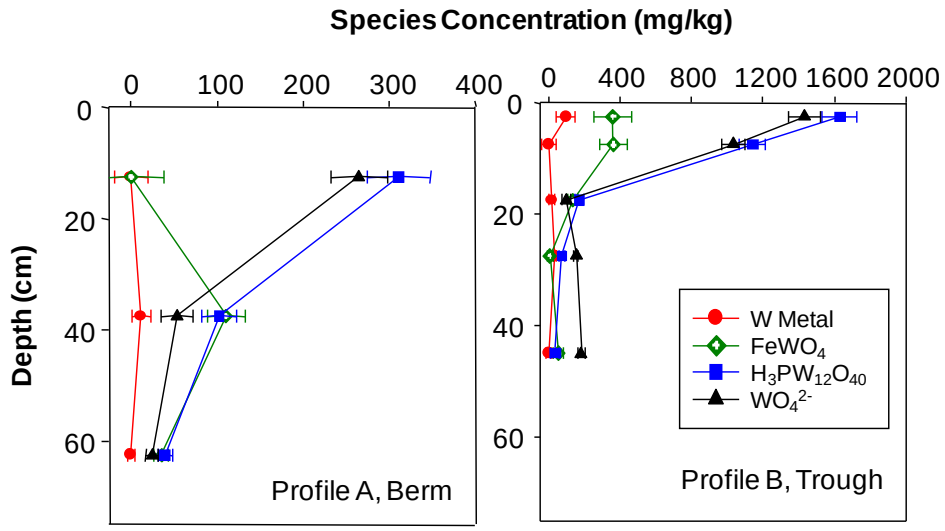

Figure 5. Changes in tungsten speciation with depth for soil profiles A and B from Camp Edwards.

In conjunction with the spectra of reference materials, it is possible to calculate the relative concentrations of component mineral (or other) phases in a soil sample. To do so, the EXAFS (or XANES) spectra of soil samples can be fit with fractional contributions of known reference spectra to calculate the fractional abundance of each component in the soil. This is done for a series of soils from the Camp Edwards site (MMRB0510 through MMRB5060) obtained from the trough of Bravo Range near Target no. 31 prior to soil removal. These spectra all have a similar spectrum, dominated by a single low frequency sine wave; this spectrum indicates a dominant W-O coordination environment (compare to spectra in Fig. 4) and clearly lacks features attributed to tungsten metal (Fig. 6). Tungsten metal would have a W-W shell resulting in a higher frequency pattern with a lot of interference (Fig. 4). In fact, little or no tungsten metal is needed to fit the experimental spectra accurately (Fig. 5), and polytungstates (Class 4 tungsten compounds) species are more prevalent than simple tungstate anions at all depths. This result is significant because it indicates, for the first time, such complexes form in soils, and they represent an appreciable fraction of adsorbed tungsten. Thus, an understanding of how these complexes form in soil systems and how they react with soil minerals is needed to accurately assess the fate of tungsten in soils.

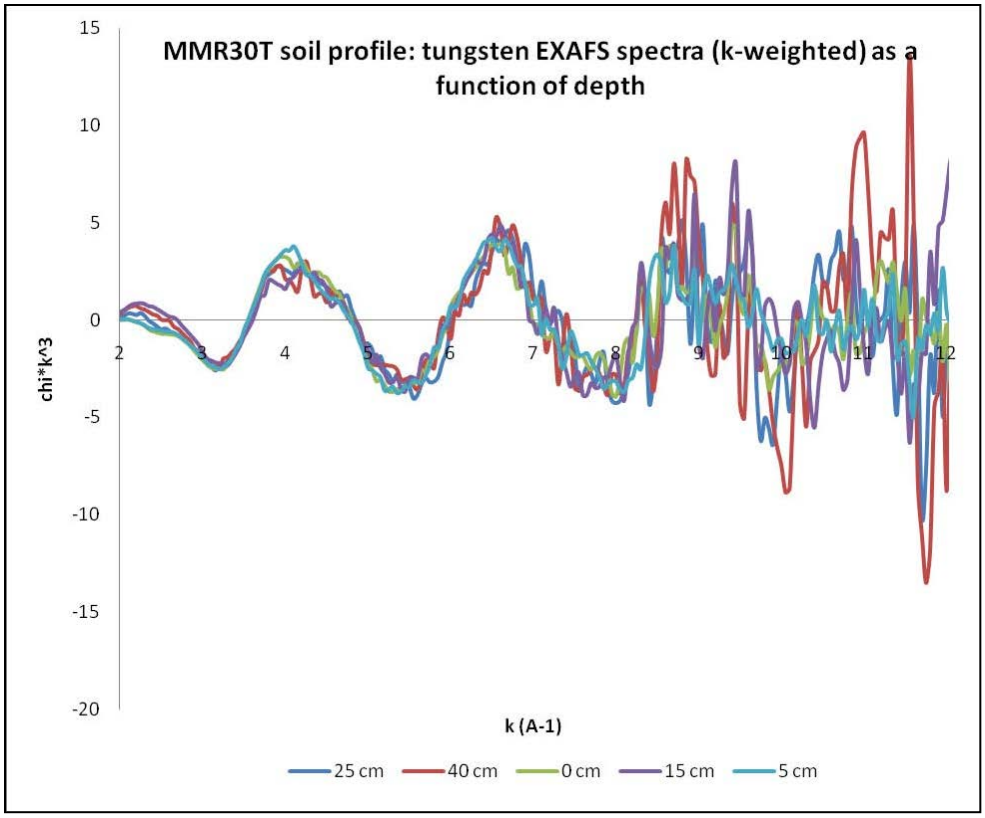

Figure 6. k^3-weighted tungsten L_3 EXAFS spectra of Camp Edwards soil profile 31T as a function of depth. The spectra all indicate that the primary coordination sphere of tungsten is dominated by oxygen at all depths, indicating extensive oxidation.

Linear combination fitting (Fig. 5) indicates polytungstates are common in soils, but it is unknown, based on the fitting, which polytungstates or POMs are present. To some extent, however, their separation is possible with theoretical fitting of tungsten spectra. Detailed theoretical fitting was performed on two Camp Edwards surface soils, Test MMRB05 obtained from the trough floor on Bravo Range near Target no. 31 and MMRBMB023S2 obtained from the middle berm region of Bravo Range, in an attempt to differentiate between conventional, homonuclear poly-tungstates (those containing only tungsten), and POMs (Table 3, Fig. 7). These soils were chosen on the basis of their high tungsten concentration (which improved data quality) and their linear combination fitting results, which implied that 50–70% of the tungsten was present as polytungstate or POM. Thus, spectral features attributed to specific polytungstates or POMS should be easily distinguished in spectrum of the soil, which re-flected the net spectrum of the soil mixture. In each case, spectral fitting (Table 3) matched the W-O and W-W shells of well characterized POMs (Table 2). Unfortunately, the spectra of both POM reference materials and these samples lack well defined P, Si, or other shells useful to distinguish

among different POMs because these features are masked by W-W shells. Nevertheless, the remarkably similar spectra of all of the examined soils suggest that POMs (rather than homonuclear polytungstates) may be important adsorbed species in these soils, although considerably more work is needed to conclusively identify the POM species in these soils.

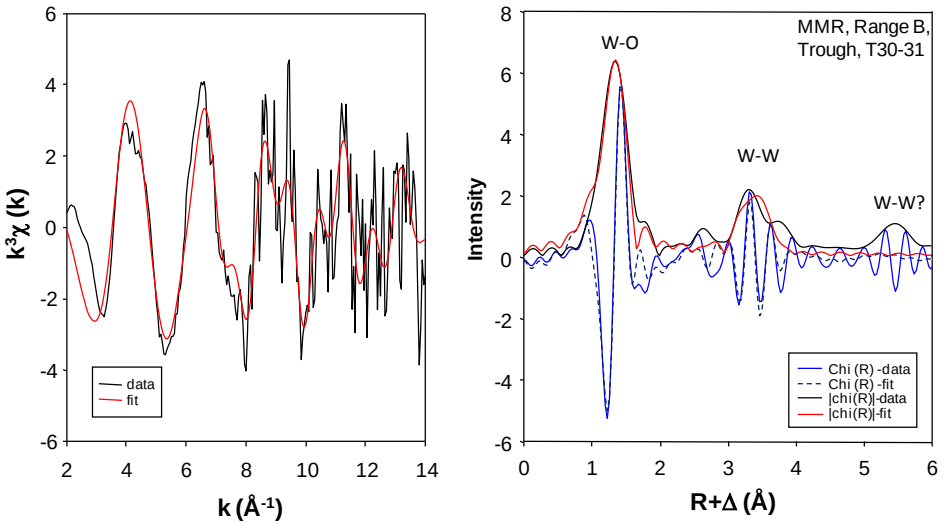

Figure 7. Detailed theoretical fits of W L_3-edge EXAFS spectra for a soil containing >50% POM or polytungstate based on least squares fitting. The fitting results are consistent with the prevalence of POMs in these soils. The close match of the spectrum (black lines) and the fit (red and dashed lines) are consistent with POMs of similar structure to the α-Keggin cluster.

Additional evidence for the presence of POMs is the known thermodynamic stability of polytungstates. Polytungstates are stable under acidic conditions, but are highly insoluble (net solubility is 1 mg L^{-1} or less under most conditions based on thermodynamic data for soil solutions at pH 7). POMs on the other hand, may be more stable at neutral conditions, and have different solubilities or adsorption behavior allowing them to be more conclusively identified based on those macroscopic properties.

The results of the EXAFS measurements can be summarized as follows:

- The speciation of tungsten is very complex, with tetrahedral tungstate, which is stable in alkaline solutions, converted to a variety of polytungstates in neutral and acidic pH solutions common to soils.
- Contaminated soils revealed changes in tungsten speciation with depth (decline of polytungstates and POMs), increased tungstate adsorption, and contained insignificant (5±7% or less) tungsten metal, consistent with XANES findings.

- Crystalline tungstate minerals such as $FeWO_4$ do not appear to represent a majority of tungsten in the soils.
- Adsorbed polytungstates or other POMs appeared to be the dominant tungsten fraction in shallow soil. The fraction of adsorbed tungstate was also significant and generally increased with soil depth while the fraction of polytungstate or POM, or both, decreased with increasing soil depth.

Table 3. EXAFS fitting parameters for select soil samples high in polytungstate.

Sample/ Fit quality	Shell	CN	R (Å)	σ^2 (Å^2)
Test 05	W-O	2[a]	1.75	0.002
MMR, Range B,	W-O	3[a]	1.92	0.007
Trough, T30-31	W-W	2[a]	3.39	0.007
X_{red}^2 = 6.72[b]	W-W	2[a]	3.70	0.008
B023S2	W-O	2[a]	1.74	0.003
MMR, Range B,	W-O	3[a]	1.93	0.008
Bullet pocket	W-W	2[a]	3.42	0.006
X_{red}^2 = 8.1[b]	W-W	2[a]	3.71	0.009

(a): Fixed during fitting based on crystallographic data.

(b): Reduced chi-squared of the fit.

– ——— , where ν is the degrees of freedom, X_{red}^2 is the observed value at a point, E is the modeled (expected) value, and σ^2 is the variance.

The coordination number (CN) is typically accurate to within ±1, interatomic distance (R) within ± 0.02 Å; σ^2 represents the variance in R (in Å^2). For all of the reference materials, E^0 was ≈ 10,207 eV.

4.1.3 X-Ray Microprobe Studies

X-ray microprobe studies are invaluable in determining the elemental abundance and phase associations of tungsten with other elements, and this information is useful for refining our understanding of which tungsten minerals are present, minerals that adsorb tungstate and POMs, and the dominant forms of tungsten in these soils.

The μXRF maps change considerably from soil depths of 0 to 20 cm, with contaminated surface soils appearing more heterogeneous than soils at depth (Fig. 8). The surface 0–5 cm of the soils (Fig. 8, upper left) contains zones of high iron, tungsten, and calcium counts (proportional to concen-

tration) separated from the bulk matrix. By 5–10 cm (Fig. 8, lower left), the regions of high tungsten counts (red) are no longer prominent, and tungsten appears to be relatively evenly distributed throughout the soil. This well-distributed tungsten is also found at the 15–20 cm depth (Fig. 8, lower right). In each map, normalized tungsten counts are positively correlated to iron counts (R^2=0.64 for the map of the 5–10 cm depth interval), although this linear correlation is not strong (R^2=0.21) for the surface soil sample (0–5 cm) because it had a relatively narrow range of concentrations, i.e., most samples exhibited very high tungsten values. At intermediate depths, the correlation contains two distinct populations: 1) very high tungsten concentrations grouped (but poorly correlated, R^2<0.2 for the group) to high iron levels, and 2) lower tungsten concentrations correlated to iron levels (R^2 =0.61). Overall, the correlation of iron and tungsten counts, or the association of high-tungsten with iron-enriched areas within the images, implies that much of the tungsten in the subsurface soil samples is adsorbed on iron minerals, presumably iron oxides.

Identification of adsorbed forms of tungstate was confirmed at a variety of points using micro-XANES spectroscopy (Fig. 9). Iron hotspots in the 0–5 cm depth interval had iron *K*-edge spectra, indicative of ferrihydrite, $Fe(OH)_3$, and, in one case, hematite, Fe_2O_3. Ferrihydrite is a high surface area iron oxide, and tungstate adsorbs strongly to its surface under normal conditions (Gustafsson 2003). In no cases were the XANES spectra indicative of ferberite, $FeWO_4$(s). Thus, although smaller quantities of this mineral may be present, it is not dominant, and adsorbed forms of tungsten (either tungstate or polytungstates) are the principal forms of tungsten in these soils. Tungsten XANES spectra can further determine if hotspots contain metallic tungsten, tungstates, or polytungstates. In each case, tungsten is present as tungsten(VI), tungstate, and polytungstate. Tungsten and iron XANES spectra in both tungsten and iron hotspots are indistinguishable—each is consistent with tungstate or polytungstates and ferrihydrite or other iron oxides. Thus, micro-XANES spectroscopy suggests most tungsten in this soil profile is one or more (poly)tungstates that are adsorbed primarily to ferrihydrite.

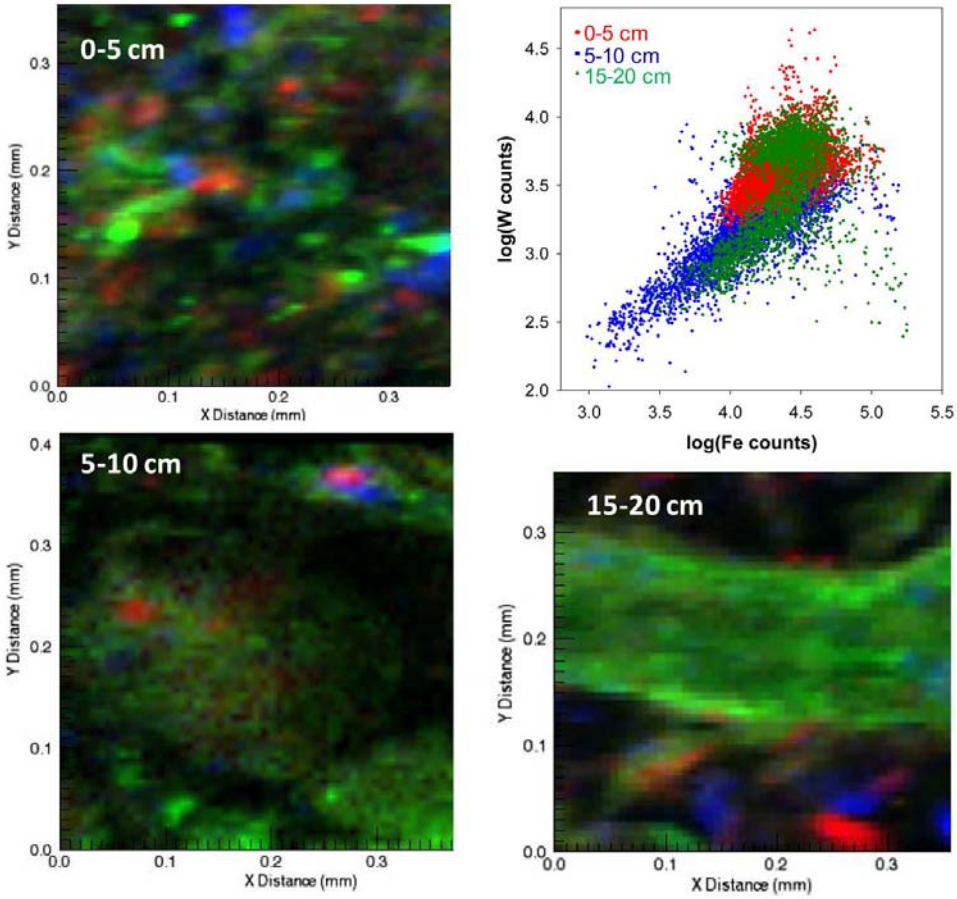

Figure 8. Microprobe XRF images of normalized iron (red), tungsten (green) and calcium (blue) fluorescence intensities for a soil collected from a trough area. Iron, calcium, and tungsten intensities in the surface soil contain numerous hotspots, but are not obviously collocated in the same grains. The correlation of log normalized iron and tungsten counts (upper right) is apparent in all samples, although it is strongest for the deeper soil samples with overall lower tungsten concentrations, and suggests adsorption of tungsten to iron phases. (Soil profile taken at Camp Edwards Range B, Trough 30-31.)

The presence of well defined, highly concentrated tungsten regions, particularly at the surface (Fig. 8), could result from the presence of tungsten-rich mineral phases, including WO_3, $CaWO_4$, or $FeWO_4$. Linear combination fitting also suggests that these mineral phases are present at this depth interval (Fig. 5). While some of these mineral phases may be present, μXRF indicates that iron hotspots are not $FeWO_4$ and does not identify any correlation between tungsten and calcium concentrations (R^2<0.1). Thus, small quantities of these minerals can form but do not appear to be dominant even in these soils.

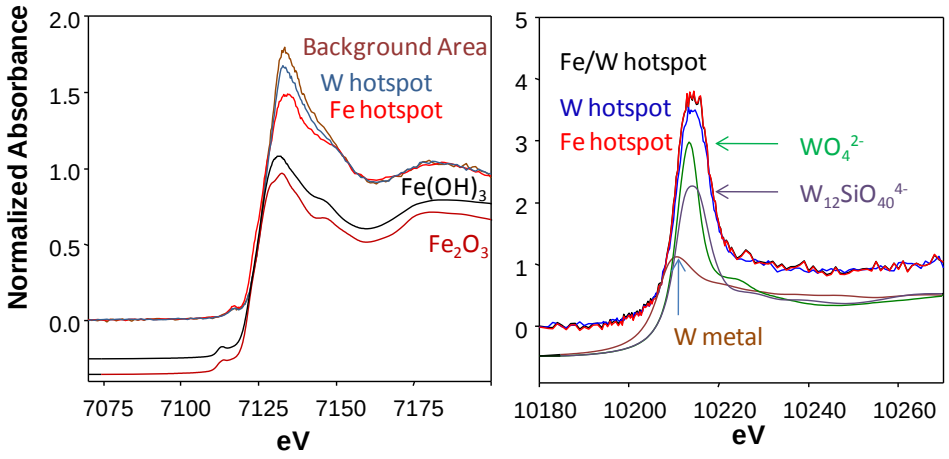

Figure 9. Microprobe iron (left) and tungsten XANES spectra (right) for representative iron and tungsten-rich spots in the XRF microprobe image in Figure 8. Selected iron and tungsten reference spectra are offset from the soils spectra for clarity. The iron spectra indicate that the iron is present as ferrihydrite and hematite, and the tungsten associated with both tungsten hotspots and background areas is a tungstate or polytungstate. (Soil sample: Camp Edwards Range B, Trough 30-31, 0-5 cm depth interval.)

Instead, tungsten-rich regions within the μXRF images appear to result from the association of high concentrations of adsorbed tungstate to reactive iron phases. These high-tungsten points also overlie the iron–tungsten correlation observed at depth, and these tungsten hotspots may just be soil aggregates with high-surface areas containing iron oxides.

Tungsten also could adsorb on other minerals, including manganese oxides, silicates, and other phases. The lack of correlation between tungsten and manganese counts implies manganese oxides are not major adsorbents of tungstate, at least in these soils. It is not possible to accurately measure aluminum or silicate counts on this beam line as configured, so it is not possible to determine the potential role of aluminosilicates for tungstate retention; however, it is expected to be relatively minor because these soils have relatively low clay contents and coarse sands have low surface areas.

To summarize:

- Surface soils between 0–5 cm contain zones of high iron, tungsten, and calcium counts from the bulk matrix. By the 5–10 cm depth interval, regions of high tungsten density associated with increased adsorption are no longer prominent, and tungsten appears to be relatively evenly distributed throughout the soil. The lower tungsten densities with

depth appear to be associated with a lack of available adsorption sites as discussed in earlier.

- Tungstates are likely adsorbed primarily to ferrihydrite and are not correlated to calcium, manganese, silicon, or aluminum in these soils, suggesting lack of covalently bonded tungsten in crystalline phases.

4.1.4 Apparent Solubility of Soil Tungsten

Based on spectroscopic results, we find that most of the tungsten in these soils is present in adsorbed forms. As such, the stability and transport properties of tungsten in soil systems should depend strongly on the relative adsorption affinity of these adsorbed forms for common soil minerals, particularly iron oxides. To further establish that adsorbed species are present, and to determine the affinity of these complexes for mineral surfaces, a series of desorption isotherms were calculated using the soils equilibrated with various volumes of water (Appendix A). These desorption isotherms for a typical contaminated soil at the site (MMRBMB036S3, which had a moderate tungsten concentration of 1626±450 mg kg^{-1}) exhibited significant desorption, approximately 10% of the tungsten desorbed, with solution tungsten concentrations reaching more than 5500 mg L^{-1} (Fig. 10A). At these high concentrations, the effective partition coefficient (K_d) was only 0.2 L kg^{-1}(eq1 and 2). Across all soils at a single solid–solution ratio, desorption also followed a similar pattern (Fig. 10B), with aqueous concentrations in some cases reaching 1500 mg L^{-1}. The considerable scatter in adsorbed tungstate concentrations is most likely caused by the variability in iron concentrations. As spectral data indicate that iron oxides are important adsorbents of tungstate, their presence should affect adsorption and thereby aqueous tungsten concentrations. To test this, we can normalize solid-phase tungsten concentrations to iron content (Fig. 10C). Indeed, much of the variation in adsorption across all soils appears to relate to differences in the iron content of the soils (Fig. 10C). Soils from the Camp Edwards site, in particular, are well described by a single isotherm, likely because of their overall similar soil properties.

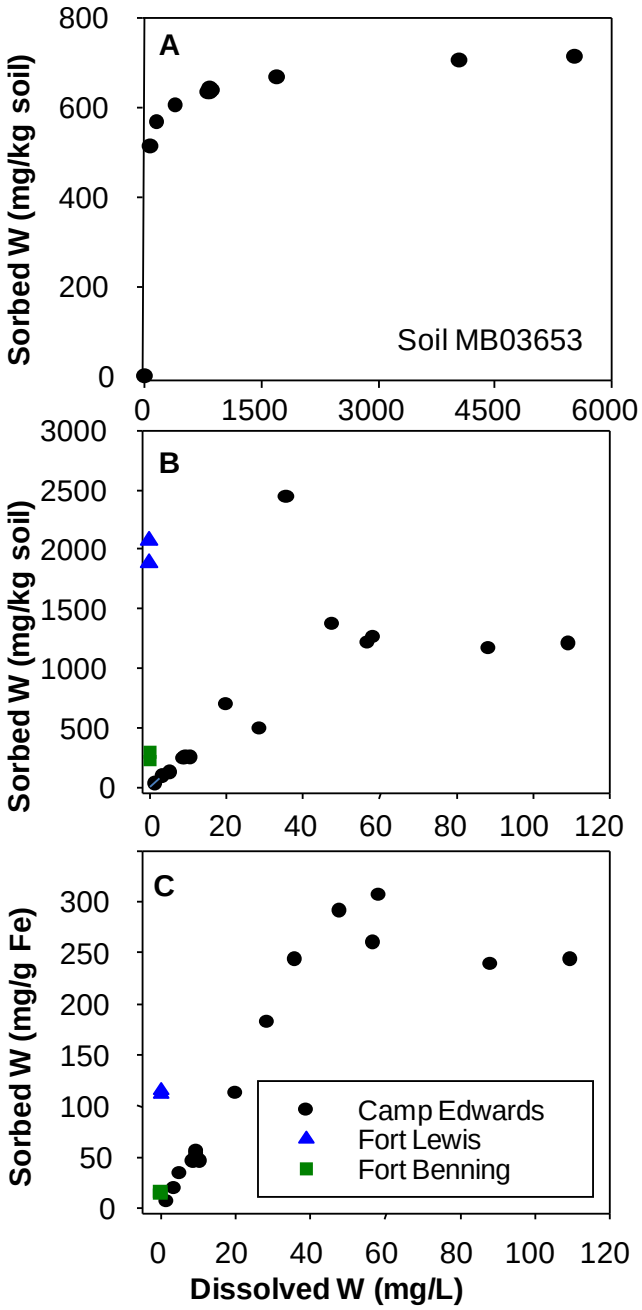

Figure 10. Desorption isotherms for soil sample MMRBMB036S3 (A) at a range of solid-solution ratios, and for all soils (B) at a fixed solid solution ratio. Accounting for variable iron concentrations in the soils (C) suggests a single isotherm, or iron oxides, control adsorption in Camp Edwards soils. The equilibrium pH for the soil sample MMRBMB036S3 is about pH 6.4 and ranges from 6–7 for most soils from Camp Edwards, and 5–6 for the Northwest and Southeast Site soils.

We can glean a considerable amount of information about what regulates tungsten concentrations in soils using the shape of adsorption or desorption isotherms. The isotherms in Figures 10A, B, and C have shapes characteristic of nonlinear adsorption phenomena, with a clearly defined adsorption maximum (or nearly so) and no apparent limits to dissolved tungsten concentrations. In contrast, if mineral dissolution controlled tungsten solubility, concentrations would be relatively uniform and limited by the concentration of one or more additional elements (for example Ca^{2+} concentrations for a $CaWO_4$ mineral). The desorption isotherms fit to both Langmuir and Freundlich equations utilizing a least-squares approach, although Freundlich isotherms yielded slightly better fits (Fig. 11). While the adsorption maxima were reasonably high, the partition coefficient, and Langmuir or Freundlich adsorption constants calculated for the desorption isotherms, all were consistent with very weak tungsten adsorption at high concentrations, consistent with the field observation of tungsten being present in groundwater at Camp Edwards (Clausen et al. 2007, 2010). Similarly weak adsorption has been observed in other contaminated sites, particularly those containing munitions (Dermatas et al. 2004; Bednar et al. 2008; Clausen et al. 2010).

Langmuir equation:

$$\Gamma = \frac{\Gamma_{max} K_L C}{1 + K_L C} = \frac{672 \times 0.034 C}{1 + 0.034 C} \quad (1)$$

Where

Γ = amount of material adsorbed (mL g^{-1})
Γ_{max} = maximum amount of material adsorbed (mg kg^{-1})
K_L = Langmuir equilibrium constant (L mg^{-1})
C = equilibrium aqueous concentration of adsorbate in solution (mg/L).

Freundlich equation:

$$\Gamma = K_F C^{\frac{1}{n}} = 379 \frac{1}{13.25} \quad (2)$$

Where

Γ = amount of material adsorbed (mL g^{-1})
n = constant (unitless)

K_F = Freundlich equilibrium constant (L mg^{-1})
C = equilibrium aqueous concentration of adsorbate in solution (mg L^{-1}).

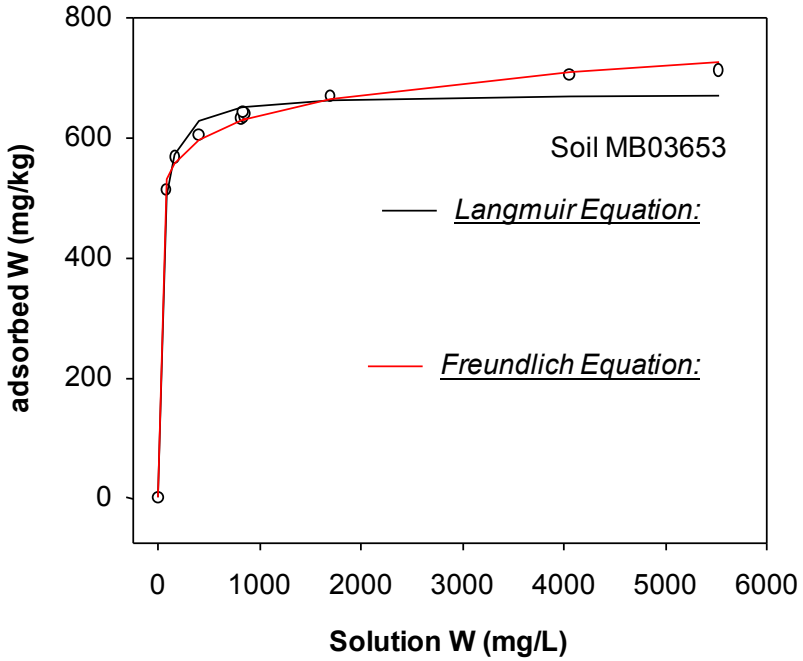

Figure 11. Langmuir and Freundlich isotherms derived for desorption experiments for soil sample MMRBMB036S3.

The soils from Southeast Site and Northwest Site have stronger adsorption than those at Camp Edwards, as evidenced by their relatively high solid-phase tungsten concentration and very slight tungsten release during desorption experiments (Fig. 10). The lower solubility of tungsten in Southeast Site and Northwest Site soils may be the result of their lower pH (their pH is 5 to 6) and higher iron oxide content as compared to the Camp Edwards soils. Tungstate is more strongly adsorbed to ferrihydrite at lower pH (Gustafsson 2003) and these soils have considerably more iron on which to adsorb. Thus, tungsten would be expected to be less susceptible to leaching losses in these soils. It is also possible differences may be attributable to the concentration of P in the soil; however, this analyte was not determined in these soils. The Camp Edwards soil was treated with MAECTITE, a P-base material. Therefore, it is likely that the Camp Edwards soil has a higher P content than the Southeast Site and Northwest Site soils. Coupled with a lower initial tungsten soil content (Clausen and Korte 2009), the speciation findings are consistent with a considerably lower amount of tungsten observed in lysimeters monitoring subsurface

soil pore water from the Southeast and Northwest sites as compared to Camp Edwards.

As shown in the Phase II tungsten work (Clausen et al. 2010), sorption was time dependent with increasing equilibration time resulting in increasing K_d values. Although the desorption and adsorption experiments are instructive in understanding tungsten behavior, relying on calculated K_d values for transport determinations is not recommended, as it is unclear whether the experimental conditions represent field conditions. For example, the equilibration interval of 24-hours used in the experiments is likely shorter than the contact time of tungsten with site soils.

To summarize:

- Adsorption and desorption of tungsten depends on available iron and its distribution for Camp Edwards soil.
- Significant desorption of tungsten is apparent for Camp Edwards soil and the isotherm can be fit with both Langmuir and Freundlich equations.
- At high concentrations tungsten is weakly adsorbed, which is probably a function of filled adsorption sites.
- Soils from the Southeast and Northwest sites adsorbed tungsten to a greater extent and were less likely to desorb tungsten than Camp Edwards soils owing to their higher iron content.
- One of the most striking results of the desorption experiments is that the concentration of tungsten in the aqueous phase reached very high values (>1000 mg L^{-1}). These high concentrations are vastly in excess of theoretical limits based on the solubility of tungstate minerals calculated by Visual Minteq (or other programs), and indicates tungsten is stabilized in solution much more than is currently recognized. This high solubility is most important in highly contaminated soils and represents a very important factor to consider in managing tungsten-impacted sites.

4.1.5 Possible Explanation for the High Solubility of Tungsten

Little information is available in the literature to corroborate and explain the adsorption behavior of tungsten in natural systems. Tungstate adsorption isotherms look qualitatively similar to those on goethite (Xu et al. 2006) and ferrihydrite (Gustafsson 2003). However, the weak tungstate retention observed in our experiments differs considerably from the rela-

tively strong adsorption behavior observed with these model systems. In fact, Gustafsson (2003) suggests tungstate adsorption is sufficiently strong to displace phosphate (a very strong adsorbent) from adsorption sites. It seems clear that tungstate is not displacing the P added (MAECTITE™) in the Camp Edwards soil (Clausen et al. 2010). This strong adsorption is related to the formation of stable tungstate surface complexes on the mineral surface—eq 3 and 4 (Gustafsson 2003):

$$\equiv FeOH^{-0.5} + WO^{\frac{2-}{4}} + H_2O + 2H^+ \Leftrightarrow \equiv Fe - OWOH_5^{-0.5}, \text{ Log } K = 19.35 \quad (3)$$

$$\equiv FeOH^{-0.5} + H^+ + H + WO_4^{2-} \Leftrightarrow \equiv Fe - OWO_3^{-0.5} + H_2O, \text{ Log } K = 14.07 \quad (4)$$

Equations 3 and 4 are derived based on measured W(VI) adsorption and use the measured solution speciation of tungsten and its adsorption in simple solutions (predominantly those containing only tungsten and background electrolytes). In general, eq 3 is favored at pH<6, while tungstate adsorption (eq 4) is more significant at neutral and higher pH, although total tungstate adsorption diminishes at pH>8 (Xu et al. 2006).

The exceptional solubility of tungstate in the soils used in this study is considerably altered by the presence of other ions in soil solutions. These ions can react with the surface independently, or influence tungsten speciation in solution and thereby indirectly influence tungsten retention. The small arms range berm soils in question at Camp Edwards were previously treated with MAECTITE™, a phosphate based proprietary material used to bind lead. This material may have filled all of the available adsorption sites, thus preventing or limiting tungsten's sorption despite its theoretical ability to displace phosphate (Clausen et al. 2010). The adsorption of other ions to the surface results in competition for the surface, which will affect tungsten adsorption, particularly if other ions react more strongly than tungstate, or are found at high concentrations. For example, tungstate adsorption influences molybdate adsorption appreciably because molybdate is adsorbed less strongly than tungstate, and the equilibria quantify this inhibition quite effectively (Xu et al. 2006). Soil solutions are complex, containing a number of possible species that could compete with tungstate adsorption, including molybdate, silicate, and carbonate, among others. Although competition undoubtedly does affect tungstate retention, the adsorption affinity or concentrations of potential competing ions are insufficient to yield measurable effects (Xu et al. 2006). Thus, the soil solution

must affect tungsten speciation in other ways. The precipitation of soil minerals also would limit tungsten concentrations below observed values, and tungsten oxides and $CaWO_4$ are both thermodynamically unstable (as indicated by the saturation indices, calculated for 100 mg L^{-1} total tungstate) except at very high tungsten concentrations in these soil solutions (Table 4).

Table 4. Solution composition and saturation indices for selected minerals for equilibrated waters from desorption experiments.

Ion	Total Concentration (mg L^{-1})[a]	Mineral	SI[b]
WO_4^{2-}	100–5,500		
Al^{3+}	0.02	W_{tot}=100 mg/L, Ca=110 mg/L	
AsO_4^{3-}	0.002	Scheelite ($CaWO_4$)	2.26
Ba^{2+}	0.02	$WO_3.H_2O$	–1.4
Ca^{2+}	12–110		
Fe^{2+}	0.05	W_{tot}=100 mg/L, Ca=12 mg/L	
$K^{+`}$	1.5	Scheelite ($CaWO_4$)	1.53
Li^{+}	0.001	$WO_3.H_2O$	–1.1
Mg^{2+}	2.0		
Mn^{2+}	0.001	W_{tot}=5500 mg/L, Ca=110 mg/L	
Na^{+}	25	Scheelite ($CaWO_4$)	2.8©
PO_4^{3-}5–75	$WO_3.H_2O$		–0.4[c]
SO_4^{2-}	0–2–5		
Sr^{2+}	0.04		
Zn^{2+}	0.1		

(a) Total concentration for the pore water following equilibration with the soil. In a few cases, the solid-solution ratio influenced the final ion concentrations. In these cases, the range reported reflects the total range in concentrations, with the concentration of the high solid-solution ratios reported first.

(b) The saturation index. $SI = \log\left(\frac{IAP}{K_{sp}}\right)$ where *IAP* is the ion activity product for the formation of the soil, and K_{sp} is the saturation index.

(c) The calculated ionic strength is very high owing to the high tungsten concentration. This result is some-what unreliable because the activity coefficients are difficult to calculate for such solutions.

The equilibrium pH was about 6.5±0.2.

The incorporation of tungstate into POMs would also affect the extent of tungstate adsorption by decreasing the fraction of free tungstate in solution. Soils have high concentrations of a number of species suitable for such incorporation in POMs, including P^{5+}, Si^{4+}, B, Zn^{2+}, and V^{3+} (Chen et

al. 2004). Of these, P^{5+} and Si^{4+} both are present in high concentrations in soil solutions and form Keggin clusters through the condensation of tungstate (eq 5 and 6):

$$12WO_4^{2-} + Si(OH)^4 + 20H^+ \Leftrightarrow W_{12}SiO_{40}^{4-} + 12H_2O \quad (5)$$

$$12WO_4^{2-} + PO_4^{3-} + 24H^+ \Leftrightarrow W_{12}PO_{40}^{4-} + 12H_2O \quad (6)$$

Although these complexes are well known, there is no information about their thermodynamic stability, so it is not possible to evaluate their prevalence in solution. However, empirical data from our studies suggest these species, in particular, are in fact present and presumably in other soil systems. First, spectral data established the presence of polytungstates in soils with pH >6.5, conditions in which the predicted solution speciation is dominated by WO_4^{2-}. In fact, spectra with high fractions of polytungstates have spectral features attributable to POMs specifically (Fig. 6), although such studies are not able to resolve shells attributed to heteroatoms, such as Si or P, because of the presence of intense W-W shells at similar distances.

An important piece of information regarding adsorption comes from the solution concentrations of tungsten in the desorption experiments. The high concentrations of tungsten from desorption experiments exceed known mineral solubilities, yet they represent minimum concentrations because additional reaction time would only result in additional dissolution. Consequently, disequilibrium processes such as a lack of mineral precipitation or slow adsorption cannot explain high solution concentrations. The desorption experiments, performed at pH 6.5, contained ~2 mM Ca^{2+} (Table 4). For all desorption experiments, tungsten concentrations ranged between 180–5500 mg L^{-1} (Appendix A). At these conditions, $CaWO_{4(s)}$ is supersaturated (W saturation is achieved at about ~1 mg L^{-1}). Thus, mineral forms of tungsten should remove tungsten from solution and impart a limit on tungsten concentrations (as long as there is adequate Ca^{2+} or other cations available in the soil solution), and mineral forms of tungstate would not dissolve in desorption experiments. So, these minerals cannot regulate tungsten levels, at least in these soils, and other factors must enhance tungsten solubility.

The stabilization of tungsten in solution, however, would allow solution concentrations to increase in response to weak adsorption. The reaction of

dissolved species with tungstate could strongly influence the stability of tungsten in soil solutions. For example, calcium and magnesium each form tungstate complexes ($CaWO_4^0$ and $MgWO_4^0$). Based on their known stability constants (log K = 2.57 and 3.03 for the formation of the complexes from WO_4^{2-} respectively), these complexes would decrease the concentration of free tungstate by about a factor of two, thereby increasing the solubility of tungsten in solution by about the same factor. Because soil solutions contain both Ca and Mg (Appendix A), these complexes are probably important in the environment, but they alone are not sufficiently stable to change the concentration of aqueous tungsten significantly. Thus, other solution complexes are needed to describe tungsten partitioning in more concentrated tungsten solutions.

The formation of aqueous POMs, which is supported by the spectral data, also would impact adsorption. Adsorption experiments were used to evaluate the possible formation of $W_{12}SiW_{40}^{4-}$, a model POM, to establish whether such complexes would influence tungsten adsorption. Adsorption isotherms (pH 7) of tungstate alone on ferrihydrite were similar to others in the literature (Xu et al. 2006). Appreciable adsorption occurred up to an adsorption maximum of 8 μmol m^{-2}, with solutions containing up to 10 mg L^{-1} tungstates (Fig. 12). The partition coefficient was approximately 40 L kg^{-1} at the adsorption maximum. The extent of tungsten adsorption changed considerably when Si was added to the system. Small quantities of Si (to an initial concentration of 1 mg L^{-1}) drastically decreased tungstate adsorption. In fact, this small concentration of dissolved Si, which is similar to that of the desorption experiments, was sufficient to decrease the magnitude of the partition coefficient to 1 or less (no significant tungsten adsorption, within the error of the measurement). This added Si would also be expected to adsorb to the solids, but is not of sufficient concentration to affect tungstate adsorption by competitive adsorption. It is, however, sufficient to convert all of the tungstate in solution to $W_{12}SiO_{40}^4$.

Thus, the effect of Si on adsorption is not from competitive adsorption and must result from its effect on tungsten speciation. Adsorption experiments were devoid of calcium or magnesium, both of which could influence WO_4 adsorption by forming stable solution complexes. Given that Si impedes adsorption so effectively in the absence of these ions, calcium and magnesium complexes do not appear to be required to influence adsorption. Experiments were not conducted to explore the relationship of P to adsorp-

tion. However, Bednar et al. (2008) assessed the impacts of this analyte and found that P could foster the formation of tungstate complexes, which will influence the degree of adsorption.

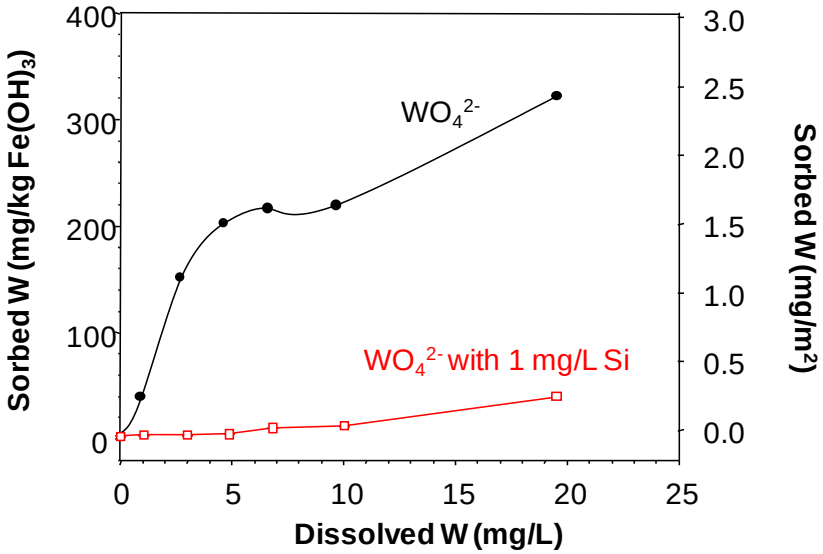

Figure 12. Adsorption isotherms for tungstate solutions (0–20 mg L^{-1}) in equilibrium with ferrihydrite (1 g L^{-1}). The addition of Si significantly diminished adsorption. The two *y*-axes apply to both lines—the left axis refers to the adsorbed tungsten in units of mass per mass, while the right axis shows adsorption in surface-area normalized units.

To summarize:

- Very high tungsten solution concentrations were observed in batch experiments, presumably because of filled adsorption sites.
- Ions present in soil solution can influence tungsten concentration and the degree of adsorption, as can the incorporation of tungstate into POMs.
- Increased Si concentrations decreased tungsten adsorption.
- The MAECTITE™ P material used to remediate lead in the Camp Edwards SAR berms may be responsible for tungsten's apparent increased mobility by preventing or limiting adsorption.

4.2 Tungsten Speciation in Water

The tungsten species present in pore-water solutions at Camp Edwards were explored using a newly developed analytical technique that separates tungsten species with size exclusion chromatography (SEC) followed by quantification with ICP-MS (Bednar et al. 2009). The method has a detec-

tion limit of 0.4 μg L^{-1} for tungstate. To resolve other species, however, higher concentrations are preferred, e.g., >1 to 1 ug/L. An earlier HPLC-ICP-MS method developed by Bednar et al. (2007) yields only semi-quantitative results. Unfortunately, this was the only method available in 2007 and was used to analyze water samples from MW-72S. Subsequent groundwater samples collected in 2009 had insufficient levels of tungsten to use the SEC-ICP-MS method and the original 2007 samples were no longer available for analysis. The concentrations of poly- and heteropoly-tungstates, as a group, can only be semi-quantitatively determined with the HPLC-ICP-MS method because they interact to some extent with the anion exchange column. In addition, resolving the speciation of tungsten requires comparison with analytical standards, which are not available for all of the species that may be present. The only standards available for comparison were sodium tungstate and polytungstate; the latter is listed as having the following composition: $Na_6[H_2W_{12}O_{40}]$ or $3Na_2WO_4 \cdot + 9WO_3 \cdot H_2O$. As noted above, polytungstates can be very complex, such that the species in the standard may not be the same as the species in the soil solution.

Outdoor dissolution tests conducted by (Clausen et al. 2010) with tungsten metal fragments suggest the production of both tungstate and poly-tungstate species in the water contacting the tungstate particles (Table 5). The results suggest polymerization is occurring directly on the tungsten metal surface and may be independent from the presence of soil (Clausen and Korte 2009, Clausen et al. 2010). It is also possible polymerization is occurring on both the tungsten metal surface as well as in the soil pore water.

The samples from the outdoor dissolution test yielded tungstate-to-polytungstate ratios of 11:1 to 19:1 (Table 5). This compares to lysimeter ratios of 4:1 to 14:1. The lower ratios from the lysimeters suggest preferential sorption of tungstate relative to polytungstate on a mass basis as compared to the dissolution tests. The ratios for lysimeters MMR-21 and MMR-30 appear relatively consistent over time.

Column test results (Clausen et al. 2010) also appear to yield higher tungstate to polytungstate ratios than those observed in the lysimeters (Table 5). However, so little polytungstate was present in the column test samples that analytical inaccuracies may affect these ratios. If the differences in ratios between the lysimeters and the column tests are real they

may be attributable to differences in degrees of saturation of the samples. The soil in the field probably oscillates between unsaturated and saturated conditions, with unsaturated conditions being more prevalent; whereas, the soil in the column tests largely remained saturated throughout the duration of the tests. As discussed previously (Clausen et al. 2010), polytungstate was not observed in the groundwater samples from MW-72S obtained on different sampling dates, possibly suggesting that polytungstate is eventually being attenuated in the Camp Edwards soil. However, as noted previously, the more sensitive SEC-ICP-MS wasn't available at the time the MW-72S sample was analyzed and subsequent samples had too little tungsten to use this method. The HPLC-ICP-MS method may have been too insensitive to see any polytungstate in the MW-72S groundwater sample.

Water samples remaining from the desorption test conducted during Phase II (Clausen et al. 2010) were analyzed with the SEC-ICP-MS method. The tungstate to polytungstate ratios for the desorption experiments conducted with sand, kaolinite clay, and goethite were largely similar to the lysimeter results (Table 5). In contrast, a much higher tungstate-to-polytungstate ratio was observed for peat, which is rich in organic matter. These results suggest the preferential sorption of polytungstate to the peat and, therefore, organic rich environments may impede the migration of polytungstates as compared to the soil conditions at Camp Edwards.

Shallow groundwater and surface water can be expected to have both tungstate and polytungstate species present. As shown above, the prevalence of tungstate versus polytungstate is variable and depends on soil conditions and the contact time (depth and migration rate). The geochemical conditions likely control the tungsten complexes formed, the degree of adsorption, and polymerization. The variables involved influencing the formation of tungstate versus polytungstate include pH level, iron, calcium, P, Si, and organic content of the soil and water, as well as depth of interest and migration rate of the water.

Table 5. Total tungsten measurements with ICP-MS compared to tungstate and polytungstate measurements using SEC-ICP-MS for batch and column test samples.

Lysimeter MMR-30, located on Bravo Range, was installed on the berm face at a depth of 4.6 m below the ground surface. MMR-30 was sampled on 30 May and 19 December 2007. The response curves for the lysimeter samples (Fig. 13) compare favorably to the curves for the polytungstate and tungstate standards, indicating that both species are present. Re-

ported total tungsten concentrations by ICP-MS can be compared to the tungstate and polytungstate values obtained with the HPLC-ICP-MS separation (Table 6). The "total" tungsten values by ICP-MS tended to be lower than the tungstate + polytungstate results by HPLC-ICP-MS. The concentrations differ because, at the time of these analyses, the HPLC-ICP-MS method was semi-quantitative. The later improvement utilizing SEC-ICP-MS (Bednar et al. 2009) allows for increased quantitative precision; however, this technique was not developed at the time of the analysis in Figure 13. It is also possible that ageing of the sample may have led to further speciation changes, precipitation, or dissolution of tungsten from associated soil particles in the samples.

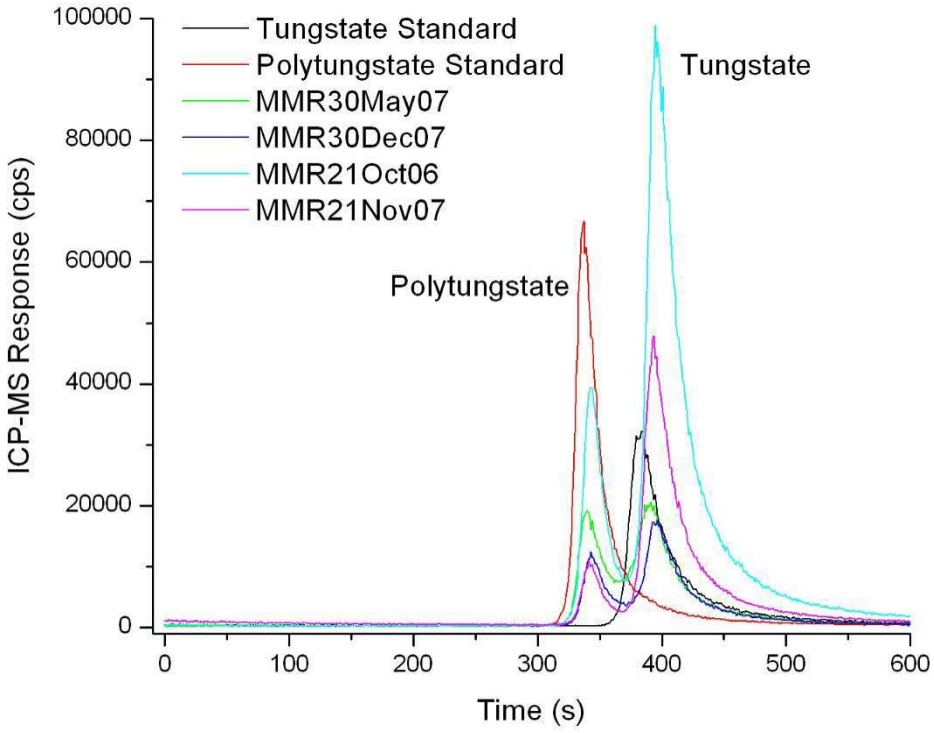

Figure 13. Speciation of tungsten in lysimeter samples from MMR-21 and MMR-30 using SEC-ICP-MS.

The lysimeter results suggest that the predominant species of tungsten present in the vadose zone at Camp Edwards is tungstate. However, the presence of polytungstate in the lysimeter samples described above shows that polymerization occurs in the vadose zone. There is a slight decrease in the tungsate:polytungstate ratios for MMR-21 vs. MMR-30, the latter approximately 3 m deeper than the former. As polytungstate is weakly sorbed to most soils, the decline in tungstate concentration in the vadose

zone pore water must be attributable to tungstate adsorption. Polymerization of tungstate is not a likely mechanism because increased polytungstate solution concentrations would result from the polytungstate being weakly sorbed to soil. Consequently, these results seem to suggest that tungstate is preferentially attenuated relative to polytungstate, which is opposite of the Bednar et al. (2008) observations.

Table 6. Total tungsten concentration compared to tungstate and polytungstate in Lysimeters MMR-21 and -30.

Lysimeter ID	Sample Date	Species Concentration (µg L^{-1})			
		Total Tungsten (ICP)	Tungstate (SEC-ICP-MS)	Polytungstate (SEC-ICP-MS)	Ratio of Tungstate to Polytungstate
MMR-21	October 2006	18,100	30,400	3,600	8:1
MMR-21	November 2007	10,000	14,100	980	14:1
MMR-30	May 2007	1,400	1,530	390	4:1
MMR-30	December 2007	1,400	1,170	230	6:1

As reported previously in Clausen et al. (2007), a sample from monitoring well MW-72S was analyzed for tungsten using the HPLC-ICP-MS speciation method of Bednar et al. (2007). The results for this particular sample were a good match with the sodium tungstate standard, with polytungstate species not being evident. This sample, collected on 10 May 2006, had a reported tungsten concentration of approximately 0.550 mg L^{-1} using ICP-MS.

Evaluation of water from MW-72S (Fig. 14) seems to suggest that polytungstates may not migrate as readily as tungstate, with attenuation occurring between 4.5 m and the 36-m deep water table. This is in contrast to the XAS soil work, which showed weak adsorption of polytungstate to Camp Edwards soil. However, it is possible that the difference between soil and water results can be explained by depolymerization that should occur at lower concentrations, although the threshold concentration required for depolymerization of complex polytungstates is not known, and the kinetics of tungstate-polytungstate equilibria are sufficiently slow (Koutsospyros et al. 2006), Therefore, it is difficult to conclude, based on the available data, how depolymerization affects transport. It is also possible that the HPLC-ICP-MS method was not particularly sensitive to polytungstate species

present in the MW-72S sample and that polytungstate is present in the groundwater. Unfortunately, insufficient sample is available to be tested with the more sensitive SEC-ICP-MS and the current tungsten concentrations in MW-72S, less than 2 ppb, are below the sensitivity of the new method. Therefore, it is possible that polytungstates were present in MW-72S but not detectable with method available at the time. In any event, the working conceptual model of tungsten concentration with depth is presented in Figure 15.

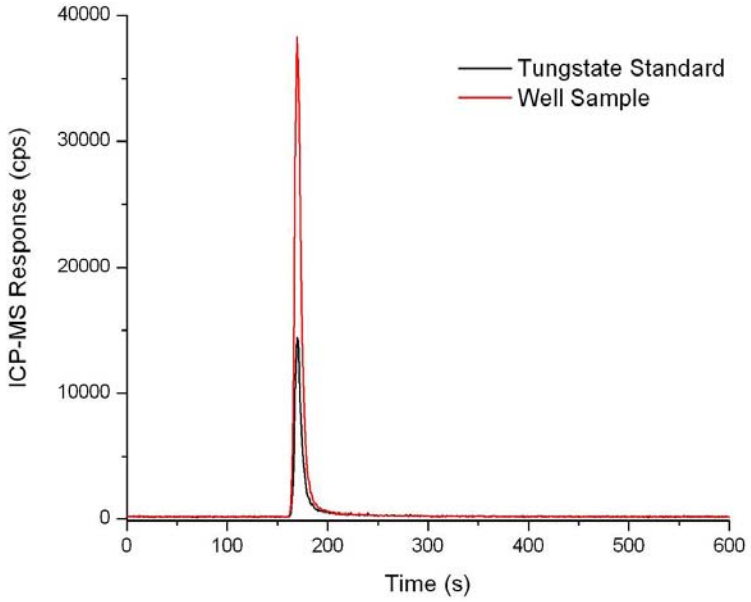

Figure 14. Speciation of tungsten in monitoring well sample MMR-72S using HPLC-ICP-MS.

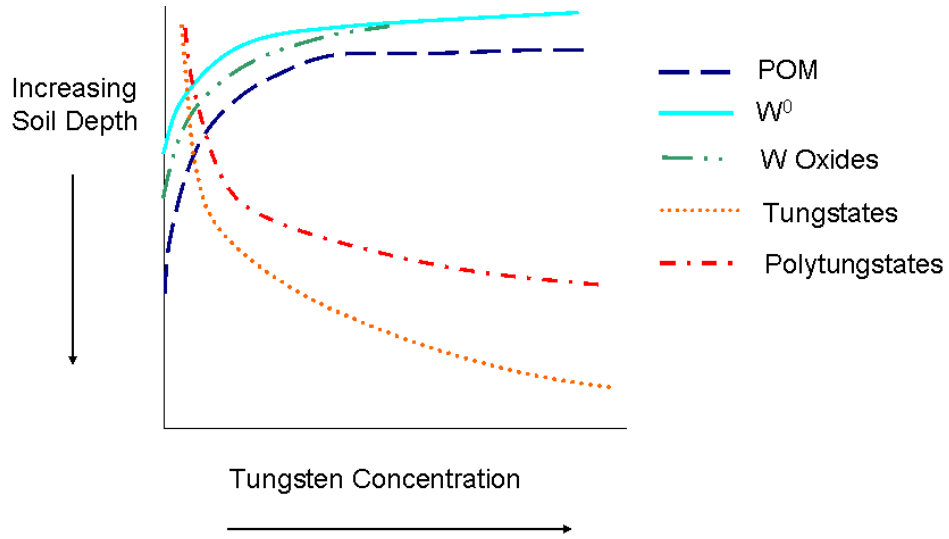

Figure 15. Relationship between tungsten concentration and soil depth.

In summary, the following observations are evident for tungsten in water:

- Dissolution tests with tungsten metal produce tungstate and polytungstate species.
- Tungstate and polytungstate species are present in vadose zone soil pore water at Camp Edwards and, although not specifically identified, POMs are also a possibility.
- The ratio of tungstate to polytungstate appears to decrease with increasing vadose zone depth, suggesting tungstate is adsorbed to a greater degree than polytungstate or the tungstate continues to undergo polymerization, increasing the amount of polytungstate and decreasing the amount of tungstate. However, if the latter were occurring, the polytungstates would have to be adsorbed to the soil. XAS data suggest polytungstates are the dominant tungsten form in soil. POMs were not specifically detected in the water, so the ratio with tungstate and polytungstate is not determinable.
- Ratios of tungstate to polytungstate in field lysimeters are relatively constant over time.
- Polytungstate was not detected in groundwater samples from MW-72S; however, the analytical method used at the time HPLC-ICP-MS may not have been sensitive enough for detection.
- Laboratory studies suggest polytungstate is preferentially sorbed to organic rich soils, impeding migration. Desorption experimental results were unclear and the tests would need to be repeated to determine the degree of desorption from organic rich soils.
- These site-specific results have broad implications for tungsten environmental transport and suggest that shallow groundwater and surface water contamination with tungstate and polytungstate can be expected. Further work will be needed to determine the potential for POMs to solubilize and be transported.

5 Conclusions

Tungsten's chemical speciation and exceptional solubility have important implications regarding its fate in environmental systems, such as the firing ranges in which tungsten munitions were used. The rapid and complete oxidation of tungsten metal is not completely surprising given its instability, but the rate and extent was somewhat unexpected. None of the soils sampled here contained significant tungsten metal, and the other tungsten species in the soil were dispersed throughout the soil matrix.

These results are based on highly contaminated soils but also have implications for the fate of tungsten and other elements in uncontaminated environments. Silica is common in the environment, and its possible complexation with tungstate to form soluble POMs may occur. These POMs would stabilize dissolved tungsten, potentially increasing soluble tungsten concentrations. The toxicity of tungsten could be strongly influenced by the formation of POMs. However, to date, no toxicology studies have been conducted with tungsten POMs. Alternatively, POMs may be sufficiently stable and large that they are soluble but not readily bioavailable, or potentially toxic. Other elements also could form soluble complexes with tungstate. This report's findings suggest that future toxicological studies should consider evaluating POMs as well as tungstate and polytungstate.

This is the first study to identify the presence of POMs in natural soils. Unfortunately, little or no data are available to confirm the presence of the POMs found in this study with other environmental systems. Polytungstates have been observed in a variety of studies (Bednar et al. 2007, 2008), but those studies do not differentiate among polytungstates, nor do they point to the presence of specific POMs. Furthermore, those studies identify polytungstates in solutions in which tungsten should be stable as polytungstates.

Stable POMs of other elements also may be formed in other environments. In fact, the recent identification of aluminum POMs in natural waters appears to significantly alter aluminum solubility and transport in the environment (Furrer et al. 2002). Similar polynuclear complexes are known for molybdate, an important micronutrient in soils, as well as some other elements. Similar complexes could influence tungsten solubility and there

is good reason to believe that the formation of similar POMs could also influence the speciation and fate of other ions in the environment.

The implications of this work can be summarized as follows:

- Tungsten metal was rapidly oxidized from metallic forms to a variety of tungstates, polytungstates, and POMs in soils, leaving little tungsten metal in the soil. The general transformation pathway is as follows:

Metallic Tungsten → Tungsten Oxide → Tungstate → Polytungstate → POM

- Although tungstates, polytungstates, and POMs were identified in soil, it is exceedingly difficult to identify specific polytungstate species or discriminate between mineral phases. Additionally, the similarity in structure between POMs and polytungstates makes their differentiation very difficult.
- The most prevalent forms of oxidized tungsten in surface soils appear to be one or more polytungstates and POMs, which represent the largest fraction of tungsten (and tungstate) in soils and are significantly more abundant than commonly occurring mineral tungstates.
- Tungstate is not predominant in surface soils, which is consistent with its low sorption potential as well as its susceptibility to polymerization. However, what little adsorption that occurs appears to be on iron oxide surfaces, such as ferrihydrite.
- Polyoxometallates have been identified in surface soil soils, the first such observation in natural soils. Polyoxometallates are relatively stable and likely to persist in surface soils and are not likely to migrate significantly.
- In general, POM and polytungstate soil concentrations decline with increasing depth. However, the ratio of tungstate to polytungstate in solution also declined with increasing depth, suggesting higher relative sorption of tungstate versus polytungstate, polymerization of tungstate to polytungstate, or both mechanisms in operation.
- Polytungstates collectively are quite soluble, with soil solutions in desorption experiments containing hundreds of mg L^{-1} tungstate. This solubility in part may be ascribable to weak retention of POMs in soil systems, although more research is needed to fully evaluate their presence and stability. Although polytungstates were not detected in groundwater samples from Camp Edwards, their presence cannot be ruled out.

- Of the many tungsten forms, the potential mobility from highest to lowest is as follows:

  Tungstate → Polytungstate → POM → Tungsten Oxide → Metallic Tungsten

- The weak retention of tungsten, in general, on soils implies that tungsten may be particularly mobile and susceptible to transport to groundwater. Observations of significant tungsten levels in unsaturated soil pore waters under field conditions at Camp Edwards (Clausen and Korte 2009; Clausen et al. 2007, 2010) substantiates tungsten mobility. Furthermore, tungsten has been detected in groundwater at Camp Edwards (Clausen and Korte 2009; Clausen et al. 2010), although the concentrations of tungsten in groundwater are much smaller than concentrations observed in shallow soil pore water. Desorption experiments indicate that soil tungstate, if not properly remediated, can potentially affect shallow groundwater resources. However, the potential mobility is a function of site geochemistry, so tungsten fate-and-transport behavior may be highly variable, necessitating assessment on a case-by-case basis.
- Presence of iron oxides such as ferrihydrite and organic matter may provide a significant control on the mobility of tungsten.

14. ABSTRACT

Synchrotron-based X-ray absorption spectroscopy (XAS) of select surface soil samples obtained from Camp Edwards, Massachusetts, small arms ranges indicate that little tungsten metal remains in the soil and that is not stable in the natural environment. X-ray absorption near edge structure (XANES) studies indicate rapid oxidation of tungsten metal to form tungsten oxides W(VI), polytungstates, tungstates, and polyoxometallates (POM) in any number of forms. Owing to structural similarities, it is difficult to identify specific species or discriminate between mineral species, although polytungstates and POMs predominate as compared to tungstates in soil. Additionally, this is the first study to identify the presence of tungsten POMs in soil. XANES spectra indicated that, as depth increased, the fraction of soil sorbed tungstate increased and both polytungstate and POM decreased, suggesting POM and polytungstates are more stable in surface soils and likely to persist, whereas tungstate is unstable. Tetrahedral tungstate is unstable in neutral and acidic pH solutions such as are present in Camp Edwards surface soils, resulting in its conversion to a variety of polytungstates. Adsorption of tungstate, although weak, appears to occur on iron oxide surfaces such as ferrihydrite. XAS studies also revealed prevalence of adsorbed polytungstates rather than discrete mineral phases. (Cont'd).

ABSTRACT (cont'd)

Soil pore waters in equilibrium with contaminated soils during laboratory experiments yielded tungsten concentrations in excess of 5000 mg L^{-1}, considerably in excess of predicted solubility limits of common tungsten minerals. These findings are consistent with field observations whereby tension lysimeters installed in the shallow vadose zone to monitor the soil pore water at the Bravo Range at Camp Edwards had tungsten concentrations as high as 400 mg L^{-1}. The high solubility and limited adsorption of tungsten in these soils is attributed to the formation of POMs such as $W_{12}SiO_{40}^{4-}$, an α-Keggin cluster, in soil solutions in addition to other polytungstates. Polytungstates are quite soluble and can yield water concentrations of several hundred mg L^{-1}. Although, not detected in groundwater, possibly because of analytical limitations, the presence of polytungstates in the vadose zone pore water at Camp Edwards suggests their presence cannot be completely ruled out. In contrast, the presence of tungstates in groundwater has been confirmed at Camp Edwards. The weak retention of tungsten, in general to soils and observation of tungsten in soil pore water and groundwater at Camp Edwards attests to tungsten's potential mobility and transport in groundwater. The slow rates of conversion between POMs, polytungstates, and tungstates are likely to affect their solubility and transport considerably. Additionally, the presence of iron oxides such as ferrihydrite and organic matter may limit tungsten mobility. In general, tungsten mobility from highest to lowest proceeds from Tungstate → Polytungstate → POM → Tungsten Oxide → Metallic Tungsten.
