# Detecting Water Quality Patterns in New Hampshire's Estuaries Using National Coastal Assessment Probability-Based Survey Data

P.R. Trowbridge and S.H. Jones

NEAEB 2008 – Bartlett, NH

March 27, 2008

# Introduction

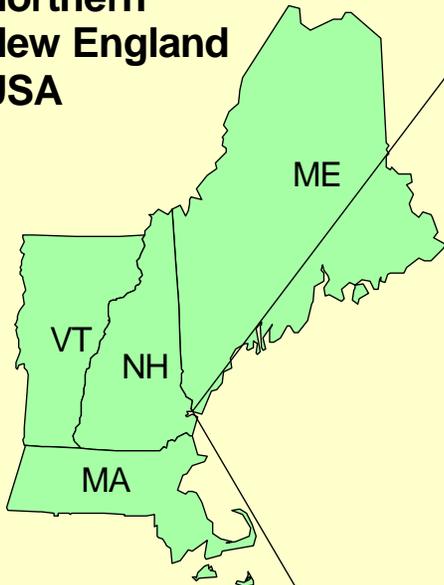

- Probability-based monitoring (PBM) of NH's estuarine waters has been done annually since 2000.
- The small study area resulted in dense sampling network.
- Fixed station monitoring for trends was also conducted at representative station.
- Climate variables (temp, rainfall) recorded for Portsmouth NH.

# Research Questions

- Can probability-based sampling data, expressed as estimated proportions, be used for trend and correlation analysis in a small estuary?
- If so, how do the results of trend and correlation analyses with probability-based data compare to the results when the same tests are run using data from traditional fixed station monitoring?

# Study Area

# Methods

- Monitoring designs
  - PBM: 25-40 station visits per year, stratified random (2000-2005), GRTS (2006)
  - Fixed Station: Monthly visits on high and low tide in 2000-2006
  - Index Period: July 1 to September 30
- Parameters
  - Temperature, Salinity, Dissolved Oxygen, Chlorophyll-*a*, Nitrogen (NH<sub>4</sub>, NO<sub>2</sub>), Orthophosphate, Suspended Solids, Fecal Coliforms.
  - Summer air temperature and rainfall in Portsmouth.

# Methods (cont.)

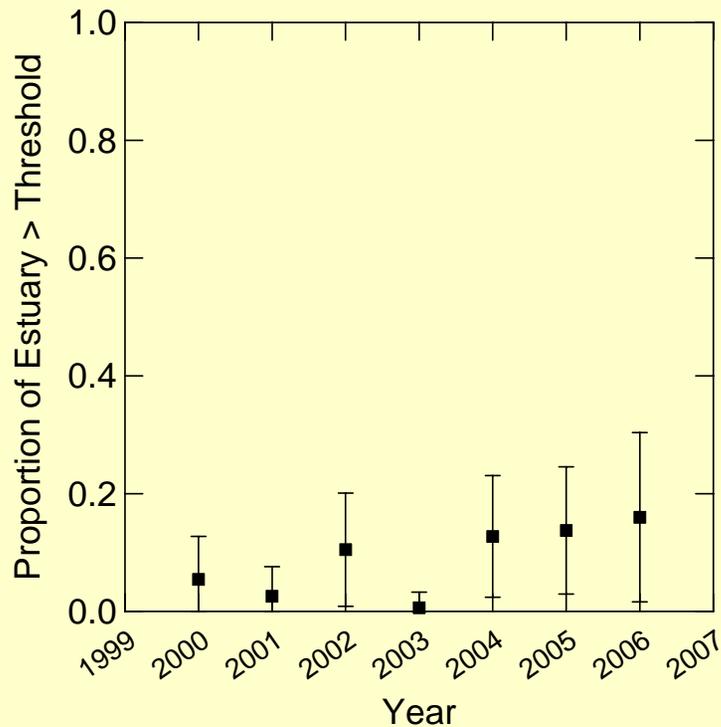

- Data Processing
  - PBM: Estimated proportions of the estuary above thresholds using Horvitz-Thompson estimator method.
  - Fixed Station: Compute median value for each parameter for each summer season.
- Statistical tests
  - Mann-Kendall test for trends in both datasets.
  - Spearman Rank Correlation test with climate variables.
  - Equal number of values from each program were used to ensure equal statistical power.

# Results-Trend Analysis

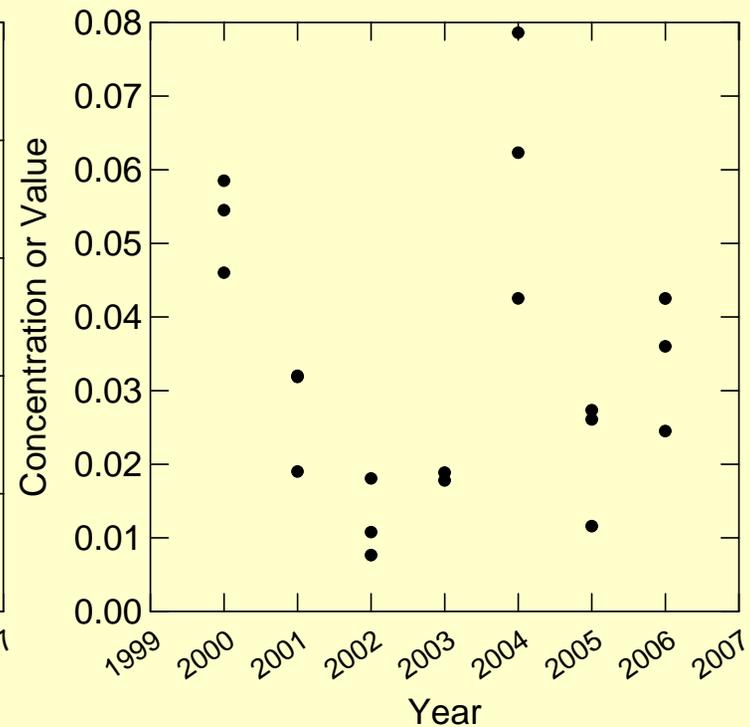

- Significant trends were detected from both datasets (0.1 significance level) but they did not match.
  - Two parameters, nitrogen as nitrate and nitrite and fecal coliform bacteria, showed significant trends using the probability-based dataset.
  - Two different parameters, chlorophyll *a* and total suspended solids, showed significant trends using the fixed station dataset.

# Nitrogen as Nitrate and Nitrite

a. Probability-Based Surveys

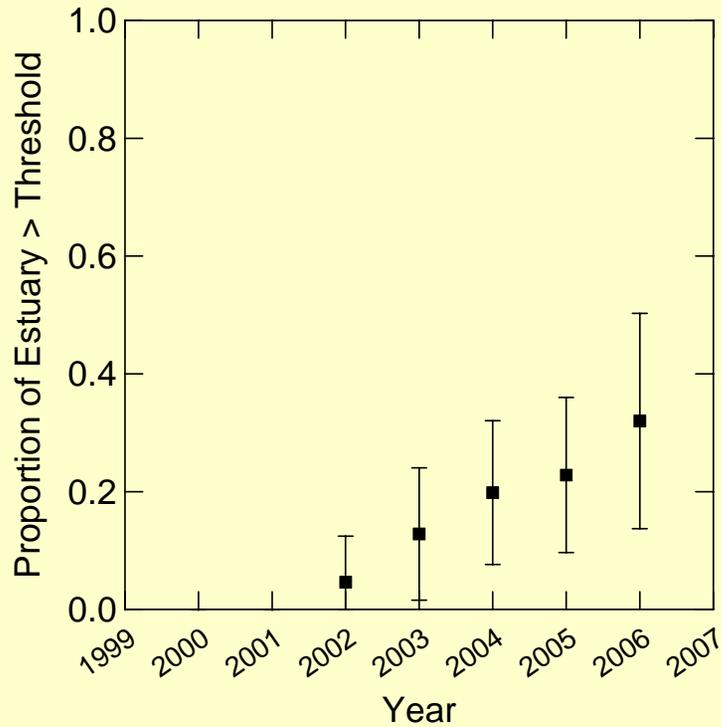

b. Grab Samples from Fixed Station

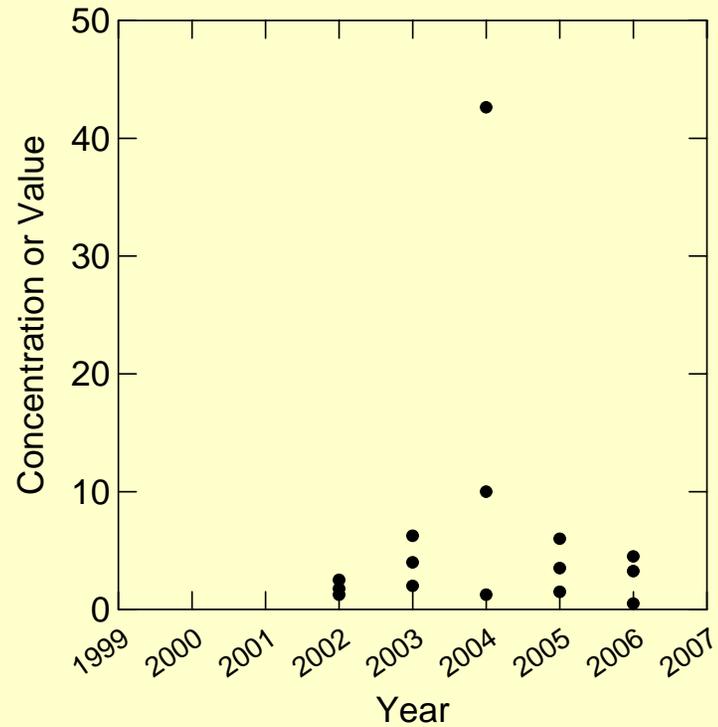

# Fecal Coliform Bacteria

a. Probability-Based Surveys

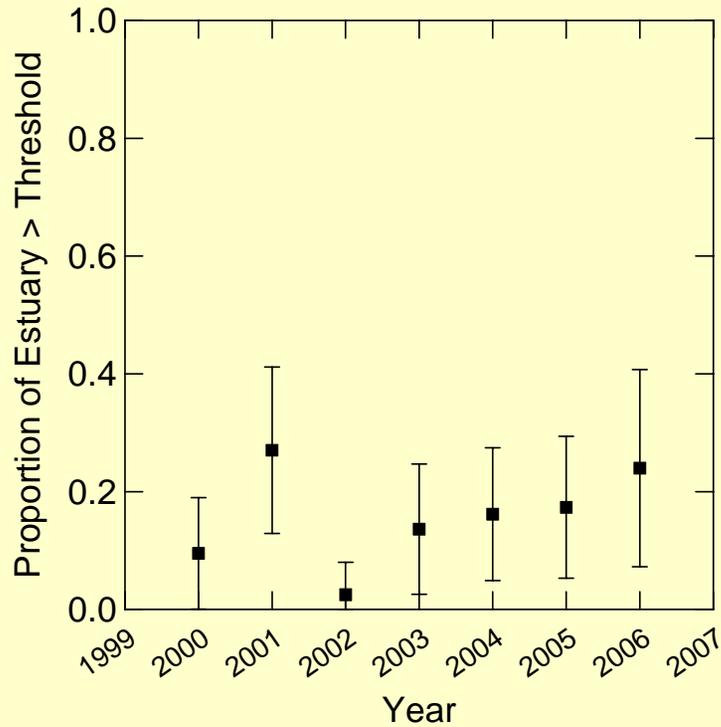

b. Grab Samples from Fixed Station

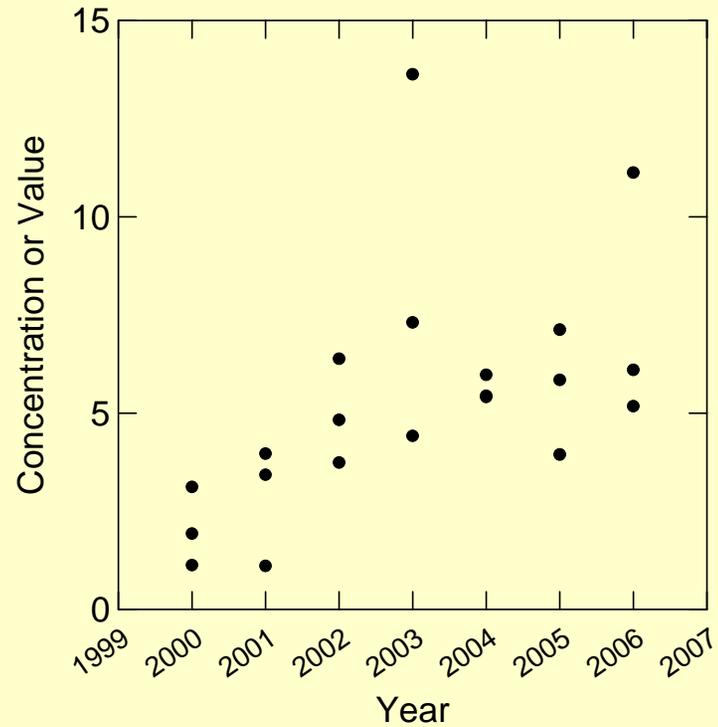

# Chlorophyll-*a*

a. Probability-Based Surveys

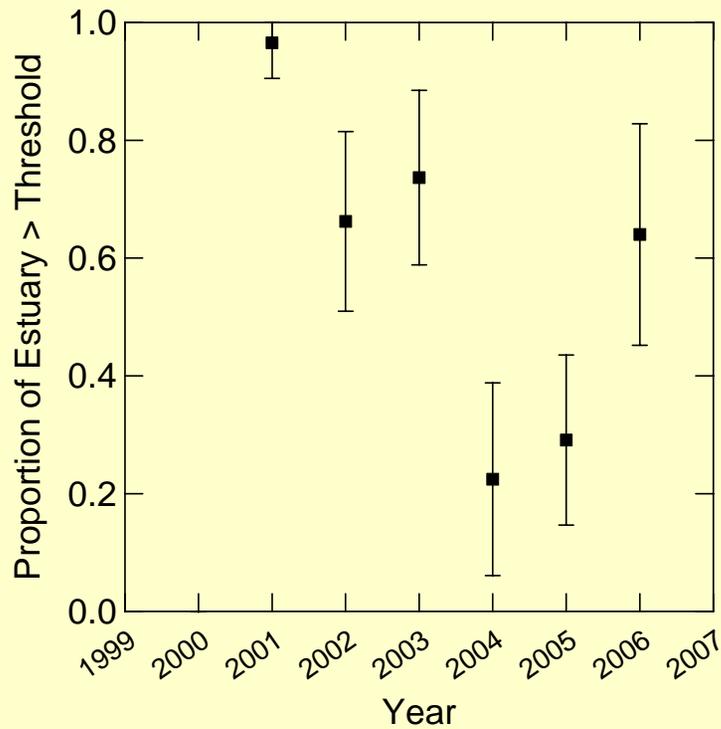

b. Grab Samples from Fixed Station

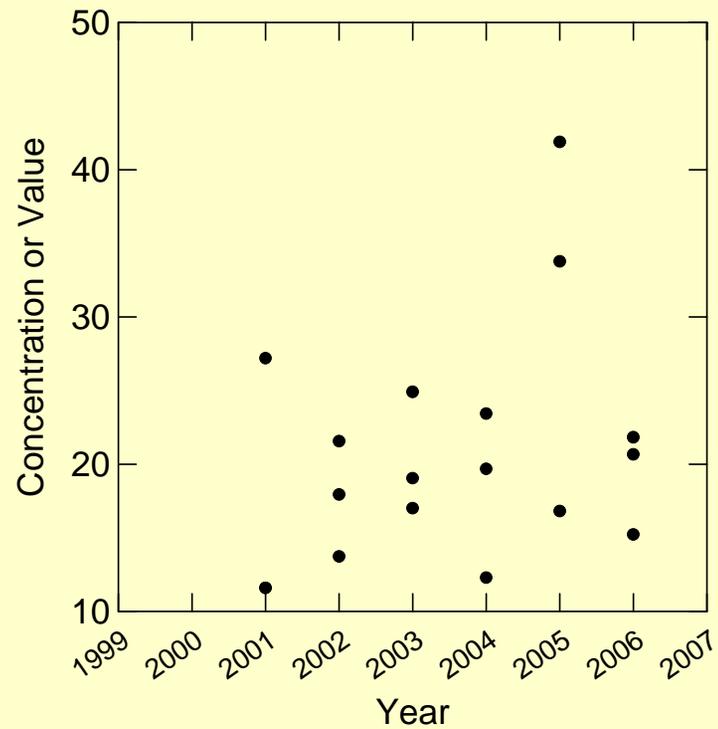

# Suspended Solids

a. Probability-Based Surveys

b. Grab Samples from Fixed Station

# Results-Climate Correlation

- Correlations detected for both datasets
- Probability-Based Monitoring:
  - Salinity and Summer Rainfall (-)
- Fixed Station Monitoring:
  - Water Temperature and Summer Rainfall (+)
  - Chlorophyll-a and Summer Rainfall (+)
  - Fecal Coliforms and Summer Rainfall (+)
  - Chlorophyll-a and Air Temperature (+)

# Conclusions

- Estimated proportions from PBM surveys were useful for detecting trends and correlations.
- However, the trends and correlations evident from probability-based surveys were different than those detected using data from monthly monitoring at a fixed station.
  - Distributed nature of the PBM design, which places stations in all sections of the estuary
  - Estimated proportions for PBM datasets reduces variability in volatile parameters

# Challenges

- If trends detected by probability-based surveys differ from the trends that have been typically detected from fixed station monitoring, the results will be confusing to managers.
- Another challenge of using probabilistic monitoring data for trend detection is the lack of agreed-upon methods for calculating trend statistics.
